Estradiol can be synthesized via two different pathways (Fig. 1). In the delta 5 pathway, the progestin pregnenolone is converted to 17 α -hydroxypregnenolone, which in turn is converted to the androgen dehydroepiandrosterone (DHEA) via 17 α -hydroxylase (CYP17A1). In the delta 4 pathway, pregnenolone is converted by 3 β -hydroxysteroid dehydrogenase (3 β HSD) to progesterone, which is then converted to androgens. Androgens are converted to the estrogens estrone and estradiol by the enzyme P450 aromatase (CYP19A1). In mammalian ovaries, estradiol is made in much greater quantities than estrone and it is also a much more potent estrogen (i.e., has greater activity on a molar basis).

Ovarian Follicular Synthesis of Estradiol: The Two-Cell, Two-Gonadotropin Model

By the 1970's there was evidence that both LH and FSH and both follicular cell types play essential roles in the synthesis of estradiol, but their relative roles were not clear (the early literature is reviewed in [Gore-Langton and Armstrong, 1994](#)). It was believed that both LH and FSH are important for follicular estradiol synthesis because both were required to restore ovarian development and estradiol secretion in hypophysectomized animals, but their relative roles were not understood. Ovarian follicles contain an oocyte and two types of endocrine-active follicular cells, granulosa and theca cells (Fig. 2). As antral follicles develop, the granulosa cells differentiate as either mural granulosa cells, surrounding the follicular antrum or cumulus granulosa cells, which surround the oocyte and interact with it in specific ways. Because no capillaries penetrate the basement membrane that separates the theca and granulosa cell compartments of the follicle, the granulosa cells and the cumulus-oocyte complex are in an avascular environment, with the follicular fluid providing their "microenvironment." Several layers of theca interna cells lie just outside the basement membrane and the thecal compartment is vascularized (Fig. 2). The two follicular cell types are thus physically separated, but they can communicate biochemically since molecules, even large ones such as LH and FSH, can pass through the basement membrane.

Experiments by Falck in the late 1950's provided compelling indirect evidence that both theca and granulosa cells are required for estradiol production ([Falck, 1959](#)). The relative roles of the two follicular endocrine cell types began to be understood in the 1970's. Before that, many reproductive biologists, including Falck, hypothesized that the theca interna cells of follicles were the major site of estradiol synthesis. They reasoned that, since the theca cell layer is vascularized whereas the inner granulosa compartment is not, it would be logical for the theca cells to be the site of estradiol synthesis. However, there was also some evidence for granulosa cells as the site of estradiol synthesis (reviewed by [Gore-Langton and Armstrong, 1994](#)).

Elucidation of the roles of the follicular endocrine cells and of the two gonadotropins was made possible in the 1970's by the availability of highly purified preparations of LH and FSH and much more sensitive methods for measuring hormones (radioimmunoassays) and by the development of methods for isolating and culturing theca and granulosa cells. One hypothesis, based partly on studies of steroidogenesis by testicular Sertoli and Leydig cells of immature rats, was that the theca cells synthesize androgens under the influence of LH and that granulosa cells cannot synthesize androgens, but can convert androgens to estradiol under the influence of FSH. This two-cell, two-gonadotropin hypothesis was first comprehensively tested with theca and granulosa cells from rat preovulatory follicles. Because of the controversy in this area, it was not clear for some time whether the results for rats applied to other mammalian species or not. The following sections will summarize findings for several mammalian species.

Rat Preovulatory Follicles

The first complete test of the two-cell, two-gonadotropin hypothesis in one species and with a single experimental model was with rats. Prepubertal rats were injected with equine chorionic gonadotropin (eCG, also known as PMSG) to initiate an estrous cycle. The

Fig. 2 Schematic diagram of a cross section through a mammalian preovulatory follicle, showing the oocyte and surrounding cumulus cells, follicular antrum, granulosa cells, theca cells, and thecal blood vessels. The size of preovulatory follicles varies greatly in different mammalian species (from ~0.5 to ~45 mm in diameter).

dose of eCG used was not superovulatory; in this model, a normal number of preovulatory follicles develops and an endogenous LH/FSH surge occurs and triggers ovulation. The developing preovulatory follicles were dissected from the ovaries on the morning of proestrus, well before the expected time of the LH/FSH surge (late on the afternoon of proestrus), and theca and granulosa cells were separated by scraping the inner granulosa cells from the basement membrane (Fig. 2). The granulosa cells are loosely connected to each other by gap junctions and were dispersed by gentle pipetting and then cultured as monolayers. The thecal layers, with cells that adhere tightly to each other, were maintained in vitro as organ cultures. Theca and granulosa cultures were maintained for 3 days, without or with highly purified preparations of LH and/or FSH.

Androgen accumulated in the medium of thecal cultures and LH increased androgen production by theca cells (Fortune and Armstrong, 1977). FSH had no effect on thecal androgen production and the effects of LH + FSH were not different from LH alone. In contrast, there were only negligible amounts of androgen in cultures of granulosa cells in the presence or absence of gonadotropins. These results confirmed earlier reports of the theca as the source of follicular androgens and established that the theca cells are a target of LH, but not FSH, action. Treatment of thecal cultures with exogenous progesterone alone did not increase androgen production and this suggested that LH increases thecal androgen synthesis by promoting the conversion of progestins to androgens.

In control medium, both theca and granulosa cells produced only very low amounts of estradiol and neither gonadotropin affected estradiol accumulation; production of estradiol by thecal cultures was greater than by granulosa cells (Fortune and Armstrong, 1978). However, the results were completely different when testosterone was added to the culture medium as a substrate for estradiol synthesis. In the presence of the androgen precursor, secretion of estradiol by granulosa cells was many-fold higher than in its absence. Estradiol was highest during the first 12 h of culture and progressively lower amounts were produced with time in culture. However, addition of FSH or FSH + LH to the medium maintained estradiol production throughout the culture period; LH alone had no effect.

Addition of testosterone to thecal cultures increased estradiol production, but gonadotropins had no further effect. In the presence of testosterone + FSH, granulosa cells produced about 8- to 9-fold more estradiol per follicle than preparations of theca from the same follicles. These results might be interpreted to mean that granulosa cells, using androgens provided by the theca cells, are the primary, but not the sole source of the estradiol produced by rat proestrous follicles. However, it is extremely difficult to remove all granulosa cells from the basement membrane by dissection and histological analysis of the thecal preparations revealed the presence of some granulosa cells attached to the theca (i.e., close to a source of androgen precursor). When theca prepared with special care to try to remove all granulosa cells ("clean" theca) was compared with preparations where the theca was scraped lightly to remove most granulosa cells ("crude" theca), estradiol production by "clean" theca was 7- to 30-fold lower than "crude" theca. These experiments provided evidence that the granulosa cells are likely the sole source of follicular estradiol in rat preovulatory follicles. Taken together, the results support the two-cell, two-gonadotropin model of follicular estradiol synthesis (Fig. 3).

Bovine Preovulatory Follicles

The experiments described above provided strong evidence for the two-cell, two-gonadotropin model in rats, but there were previous reports in the literature of thecal production of estradiol in other species and it was not clear to what extent the model might apply to other mammalian species. Hence, the two-cell, two-gonadotropin model was not uniformly embraced by reproductive biologists. Cattle were the next species to be examined extensively via experiments that allowed direct comparison to the studies in rodents. Cattle have much larger preovulatory follicles than rats (~15 mm vs. ~1 mm diameter) and a much longer estrous cycle (average about 21 days vs. 4 or 5 days for rats) and they usually ovulate only one follicle versus 10–12. The bovine follicular phase, initiated by the regression of the corpus luteum and a decline in circulating progesterone, is 2–4 days long and estrus occurs at around the time of the peak of the gonadotropin surge; ovulation follows about 29 h later.

Theca and granulosa cells interact to promote estradiol production

Because the length of an individual bovine estrous cycle is not readily predictable, preovulatory follicles at a stage similar to those in the experiments with rats were obtained by daily measurements of progesterone and removal of the preovulatory follicle about 24 h after progesterone first decreased to <1 ng/mL, which is indicative of luteolysis. The preovulatory follicle was dissected from the ovary and the granulosa cells were separated from the theca interna by scraping them from the basement membrane. As with

Fig. 3 The two-cell, two-gonadotropin model of estradiol synthesis in rat proestrous follicles. LH binds to receptors on theca cells to stimulate them to synthesize androgens. Granulosa cells cannot convert progestins to androgens, but convert exogenous androgen to estradiol via the enzyme aromatase, which is induced and maintained by FSH.

the studies on rat proestrous follicles, pieces of theca interna were maintained in organ culture and granulosa cells were dispersed and grown in monolayer cultures. The large size of bovine preovulatory follicles allowed all treatments to be applied to thecal and granulosa cultures from each follicle. Theca cells secreted androgen into the medium, primarily in the form of androstenedione, and LH, but not FSH, stimulated its production. Accumulation of estradiol in the medium of thecal cultures was negligible. Granulosa cells did not secrete androgens, even in the presence of exogenous progesterin precursor, but readily converted exogenous testosterone to estradiol (reviewed in [Fortune and Quirk, 1988](#)).

Importance of gonadotropin concentration

In initial experiments with bovine follicular cells in vitro, neither FSH nor LH stimulated the aromatization of testosterone to estradiol by granulosa cells and the effects of LH on thecal androgen production were exerted primarily during the first day of culture. Later dose-response experiments revealed that low doses of LH (2–4 ng/mL) or FSH (1–2 ng/mL) stimulated androstenedione or estradiol (in medium with testosterone) production by theca or granulosa cells, respectively, over the course of 3-day cultures ([Berndtson et al., 1995](#)). In contrast, higher doses of the gonadotropins did not stimulate (androstenedione) or inhibited (estradiol) accumulation of those steroids, but higher doses stimulated progesterone secretion by both cell types and initiated oxytocin secretion by granulosa cells ([Berndtson et al., 1995](#)). These experiments both confirmed the two-cell, two-gonadotropin model for bovine preovulatory follicles and underscored the importance of the concentration of gonadotropin used in vitro. A narrow range of low doses of LH and FSH promoted a follicular-phase profile of steroid production (androgen and estradiol), whereas higher doses luteinized the cells in culture. This makes physiological sense, because follicular cells are exposed to low circulating concentrations of LH and FSH during the follicular phase of the cycle in vivo and they increase secretion of estradiol into the blood under those conditions. In contrast, the LH/FSH surge rapidly decreases follicular androgen and estradiol secretion in vivo and promotes production of the luteal phase steroid progesterone (and in cattle and sheep, the luteal peptide hormone oxytocin).

Theca and granulosa cells interact to promote thecal androgen production

In the course of experiments with both rat proestrous follicles and bovine preovulatory follicles, preparations of follicle wall (theca with granulosa cells attached) secreted more androgen than isolated theca. These results suggested the hypothesis that granulosa cells increase the capacity of theca cells to synthesize androgens by providing them with progesterin precursor. When bovine thecal cultures were treated with graded doses of pregnenolone or progesterone, pregnenolone was much more effective than progesterone at increasing androstenedione production (reviewed in [Fortune and Quirk, 1988](#)). This suggests that bovine theca cells use the delta 5 pathway to synthesize androgens ([Fig. 1](#)). Although secretion of pregnenolone by bovine granulosa or theca cells, cultured without or with gonadotropins, is low, adding estradiol to the culture medium increased pregnenolone in the culture medium 11-fold (granulosa) or 3-fold (theca) and decreased progesterone secretion by both cell types (reviewed in [Fortune and Quirk, 1988](#)). The concentrations of estradiol that produced maximal effects were similar to concentrations that granulosa and theca cells of preovulatory follicles are exposed to in vivo (i.e., concentrations in the follicular fluid; [Fortune and Hansel, 1985](#)).

These results, summarized in [Fig. 4](#), indicate that interactions between the two follicular cell types to promote estradiol production go beyond the theca providing the granulosa cells with androgen precursor. The results suggest that the granulosa cells provide progesterin precursor in the form of pregnenolone to the theca cells to enhance their production of androstenedione. As estradiol production increases during follicular development, its concentration in the follicular fluid increases to levels that inhibit the delta 4 pathway in both cell types, thus further driving androgen production via the delta 5 pathway ([Fig. 4](#)). This is a positive feedback loop in which follicular estradiol increases its own production. The LH/FSH surge breaks this loop by decreasing androgen and

Fig. 4 Interactions between theca and granulosa cells of bovine preovulatory follicles that promote estradiol production. In addition to the interactions shown in [Fig. 3](#), experimental evidence suggests that granulosa cells interact with theca cells to increase their synthesis of androstenedione by providing them with progesterin precursor in the form of pregnenolone and that high intrafollicular concentrations of estradiol inhibit the $\Delta 4$ pathway, promoting androgen synthesis by conversion of pregnenolone via the $\Delta 5$ pathway.

estradiol synthesis and increasing progesterone production by the periovulatory follicle and the surge induces other changes that culminate in ovulation of the oocyte and luteinization of the remaining follicular cells.

Porcine Preovulatory Follicles

In porcine follicles, the FSH receptor (FSHR) and its mRNA are localized exclusively to the granulosa cell layer. During the later stages of growth of preovulatory follicles, but shortly before the gonadotropin surge, FSHR and its mRNA decrease and granulosa cells begin to acquire LH receptors. In contrast, theca cells express LH receptors throughout follicular development, but never have FSH receptors. In granulosa cells, FSH signaling increases aromatase activity, allowing the cells to synthesize estrogens from androgen precursors. *CYP19A1* mRNA, aromatase immunoreactivity, and/or estradiol secretion were detected in theca cells in some studies, albeit at lower levels than in granulosa cells, but were not detected in other studies. Theca cells express mRNAs for enzymes necessary for progestin and androgen synthesis, whereas those mRNAs have little or no expression in porcine granulosa cells. Taken together, these findings suggest that developing porcine preovulatory follicles produce large quantities of estradiol via interactions between the theca and granulosa cells in which the theca cells are stimulated by LH to produce androgens that are converted to estradiol by granulosa cells under the influence of FSH. It is not clear whether porcine theca cells also contribute to follicular estradiol production to a limited extent or not. This area of research was reviewed recently by [LaVoie \(2017\)](#).

Equine Preovulatory Follicles

Horses differ from other domestic species and from rodents and primates in their long period of estrus (4–6 days) at the end of the follicular phase. In addition, the preovulatory follicle is much larger than in other species (40–45 mm in diameter) and ovulation occurs only at a specific region of the ovary, the ovulation fossa. Initial studies on the relative roles of equine theca and granulosa cells led to a model which held that granulosa cells produce progesterone, whereas theca cells produce estradiol, perhaps using progesterone from the granulosa cells as precursor. In vitro studies in the early 1990's, similar to those that supported the two-cell, two-gonadotropin model in rats and cattle, led to a different conclusion about the source of follicular estradiol ([Sirois et al., 1991](#)). Theca and granulosa cells were isolated from preovulatory follicles in early estrus (day 1–2 of estrus) and cultured for 3 days. Theca cells secreted primarily androstenedione and its production was increased by LH, but not by FSH. In contrast, theca cells secreted only negligible quantities of progesterone and estradiol. Granulosa cells had very limited to no ability to produce androstenedione and this is consistent with their secretion of only very negligible amounts of estradiol in control medium. However, when testosterone was added to the medium, granulosa cells secreted about 170-fold more estradiol over 3 days of culture, but neither gonadotropin affected estradiol production. Granulosa cells secreted progesterone and its production was stimulated by both gonadotropins, especially during the second and third days of culture.

The results of the studies in vitro support the model of cooperation between theca and granulosa cells in the production of estradiol, with the theca cells producing androgen under the influence of LH and granulosa cells aromatizing androgen to estradiol. These conclusions are supported by later molecular studies that localized *CYP17A1* to the theca cells and *CYP19A1* to the granulosa cells of equine preovulatory follicles ([Watson et al., 2004](#)). The role of the gonadotropins in aromatization by equine granulosa cells is less clear. Dose-response studies might clarify this issue, based on the results for cattle where only low doses of FSH increased the conversion of testosterone to estradiol ([Berndtson et al., 1995](#)).

Primate Preovulatory Follicles

Investigations of the relative roles of theca and granulosa cells and of LH and FSH in the production of estradiol by preovulatory human and nonhuman primate follicles have yielded results that support a two-cell, two-gonadotropin model (reviewed by [Zeleznik and Benyo, 1994](#); [Strauss and Williams, 2014](#)). Primate theca cells synthesize and secrete aromatizable androgens, primarily androstenedione and LH, but not FSH, stimulates androgen synthesis and secretion. Granulosa cells do not make androgens, but can aromatize exogenous androgens to estradiol under the influence of FSH.

Regulation of Steroidogenesis at Earlier Stages of Follicular Development

Preovulatory follicles are by far the most active in producing estradiol, but it is interesting that what is known about steroidogenesis by earlier follicular stages is also consistent with the two-cell, two-gonadotropin model. LH and FSH receptors have been detected on theca and granulosa cells, respectively, from early preantral stages onwards. Mouse ovaries began to secrete sex steroids and to respond to LH and FSH in vitro as early as 7 days of age, when only primordial, primary, and early secondary follicles are present ([Fortune and Eppig, 1979](#)). In those studies, LH stimulated progesterone and androgen production, whereas FSH stimulated the conversion of exogenous androgen to estradiol.

Fetal ovaries produce steroids, even before follicles have formed and the level of ovarian steroid production varies over the course of gestation. In cattle, fetal ovarian production of estradiol and progesterone is higher before follicles start to form than during follicle formation. The results of in vitro studies on the regulation of fetal ovarian steroid production in ovaries obtained just before the initiation of follicle formation suggest that two different steroidogenic cell types are involved, with LH promoting

androgen production and FSH responsible for increasing aromatization (Allen et al., 2016). Exactly which fetal ovarian cells are involved remains to be determined. Taking all these results together suggests that the two-cell, two-gonadotropin model is an inherent mechanism that allows mammalian ovaries to produce estradiol at various stages of ovarian and follicular development.

Summary and Additional Considerations

The literature reviewed above for various mammalian species supports a two-cell, two-gonadotropin model that describes an interaction between the two follicular endocrine cell types, responding to different gonadotropins, that enables the dramatic increase in estradiol to levels high enough to elicit the LH/FSH surge that triggers ovulation. All the evidence thus far points to this model as the mechanism for preovulatory estradiol production in mammals and probably for follicular synthesis of estradiol at all stages. However, there may be modulations of the basic model that are species-specific.

It seems clear that only theca cells can synthesize androgens from progestins. Some species (cattle, sheep, primates) use predominantly the delta-5 pathway to produce thecal androgen, whereas others use the delta 4 pathway (guinea pigs) or are able to use both pathways (rats, pigs) (reviewed by Conley and Bird, 1997). That LH stimulates androgen synthesis is also clear; with the use of reasonably pure preparations of gonadotropins, there have been no suggestions that theca cells are a target for FSH. There have been reports for some species that theca cells can synthesize estradiol. However, theca cells can appear to produce estradiol if the preparations contain contaminating granulosa cells, which can readily convert the androgens produced by the adjacent theca to estradiol. In addition, theca cells may contain estradiol that has diffused in from the granulosa cell compartment in vivo and this may diffuse out of the cells in the early hours of culture. When immunohistochemistry is used, the antibodies may cross-react with similar steroidogenic enzymes and so results are not definitive unless such cross-reactivity is ruled out. These considerations can make it difficult to evaluate reports of thecal estradiol production. It is possible that the theca produces a low level of estradiol in some species (e.g., pigs), but that level would be many-fold less than the levels produced by granulosa cells.

It seems clear that granulosa cells do not produce androgens (although small amounts may diffuse from the cells during the early hours of culture), but do convert androgens to estradiol and that FSH induces the aromatase enzyme (CYP19A1) that converts androgens supplied by the theca cells to estradiol. As follicular development proceeds and follicles approach the time of the LH/FSH surge, granulosa cells also acquire LH receptors. It is not clear if these receptors are acquired solely in preparation for granulosa cells to respond to the LH surge or if they enable granulosa cells to convert androgens to estradiol in response to both LH and FSH, thereby increasing follicular capacity to produce estradiol. The latter possibility is frequently assumed, but in at least one species (cattle) granulosa cells with LH receptors did not aromatize androgen in response to LH (Berndtson et al., 1995). Furthermore, in species where the corpus luteum produces estradiol, an increase in aromatization in response to LH can be due to luteinization of the granulosa cells in vitro. As discussed above, the dose of LH or FSH used in vitro is critically important. Thus, whether the LH receptors acquired late in follicular development by granulosa cells directly increase aromatization is still uncertain and there may be as yet unappreciated species differences.

The production of a high, and continuously increasing, level of estradiol is, arguably, the most important endocrine function of developing preovulatory follicles. This article has reviewed the basis for the current model of estradiol production via interactions between the two endocrine cell types, responding to different gonadotropins. However, there is extensive evidence that a number of other hormones and growth factors, particularly intra-follicular factors, impinge on this basic model to modulate steroid biosynthesis (e.g., steroids, activin, inhibin, and various growth factors). Consideration of these factors is beyond the scope of this article and readers are referred to reviews that consider this topic (Hillier, 2001; Macklon et al., 2006; Strauss and Williams, 2014).

Hormone Effects on Follicular Growth and Differentiation

The Hypothalamic–Pituitary–Gonadal Axis

When the hypothalamic neurons produce the neuropeptide *gonadotropin-releasing hormone* (GnRH), GnRH is released into the portal vessels in pulses (Maffucci and Gore, 2009). The biological regulation of GnRH secretion is controlled by the pulsatile mode and keeps continuing throughout the reproductive lifespan in female. The pulse of GnRH occurs every 1–2 h in primate, while it does at intervals of about 30 min in rat (Maffucci et al., 2008). The GnRH from GnRH neurons is synthesized as a prehormone in the anterior hypothalamus and secreted as a 10-amino acid peptide hormone. The pulsatile pattern of decapeptide GnRH induces secretion of the gonadotropin hormones—*follicle-stimulating hormone* (FSH) and *luteinizing hormone* (LH)—from gonadotropes in the anterior pituitary, also in a pulsatile fashion. FSH and LH are comprised of a unique β -subunit and a common α -subunit (Thompson and Kaiser, 2014). In the ovary, FSH stimulates early follicle growth while LH causes ovulation of the dominant or Graafian follicles. They also stimulate the ovarian follicles to secrete the sex steroid hormones—*androgens*, *estrogens*, and *progesterones*—as well as the peptide hormones *activin*, *inhibin*, and *folliculin*. In addition to acting locally on the ovary, these hormones feed back to modulate the secretion of FSH and LH through a positive/negative feedback system, forming the hypothalamic–pituitary–gonadal (HPG) axis. This homeostatic feedback system is critical for maintaining the regular fluctuations in serum levels of FSH and LH and ovarian production of steroid and peptide hormones during the follicular and luteal phases of the menstrual cycle.

Hormones at Puberty

In the fetus and newborn babies, the levels of FSH and LH are high, but then drop quickly and remain low until puberty (Kuri-Hanninen et al., 2014). The amplitude of LH pulses, stimulated by the pulsatile release of GnRH from the hypothalamus, changes from hour to hour prior to puberty; however, FSH and LH do not reach sufficient levels to initiate gonadal function. At early puberty, blood levels of FSH and LH begin to rise at night and pulses increase in amplitude and frequency. Primordial follicles are selected from the ovarian reserve to enter folliculogenesis, and the estrogens from these growing follicles acts as an agonist to the increasing gonadotropin secretion before menarche. As puberty progresses, GnRH induces sufficient release of FSH and LH from the pituitary to trigger the first ovulatory surge. When the uterus synchronizes to the hypothalamic–pituitary–ovarian axis hormonal cycles, the endometrium builds (follicular phase) and is shed (luteal phase) with each cycle (Fig. 1).

Hormone Production and Action Through the Stages of Folliculogenesis

The female fetal ovary contains 6–7 million germ cells contained within primordial follicles (Findlay et al., 2015). Germ cells enter meiosis at 7–15 weeks of gestation and maintain meiotic arrest until puberty. Most of the primordial follicles in the fetal ovary are lost before birth, leaving only 1 million distributed into each ovary at birth. In humans, the total number of primordial follicles at birth represents the ovarian reserve—a measure of reproductive capacity and endocrine health. Here, we introduce the critical bioactive steroid and peptide hormones involved in the selection of follicles from the reserve to resume meiosis and grow, as well as the processes of folliculogenesis and ovulation. Primordial follicles contain a single immature oocyte covered in a layer of squamous-shaped pregranulosa cells. Primordial follicles exist in a dormant status and do not produce any steroid hormones. The phosphoinositide 3-kinase (PI3K) pathway plays a central role in the activation of quiescent primordial follicles and initiation of folliculogenesis (Zheng et al., 2012). PTEN and FOXO3 inhibit PI3K, which ensures dormancy of primordial follicles. Internal and external signals inhibit PTEN and FOXO3, releasing the block and allowing primordial follicles to develop into primary follicles. The squamous pregranulosa cells develop into cuboidal-shaped granulosa cells during this transition.

The activated follicle progresses through the primary and secondary (preantral) stages, which are characterized by oocyte growth, granulosa cell proliferation, and acquisition of theca cells (Zhang and Liu, 2015). Early growth of follicles relies on various autocrine and paracrine factors between the oocyte and the somatic cell compartments of the follicle and is not dependent on pituitary gonadotropin signals. The granulosa cells of primary follicles start to make *activins* and *inhibins*, express proliferation markers, and form multiple cell layers around the oocyte. Stromal cells are recruited to form the outer theca cell layer and produce secondary follicles. In each human menstrual cycle, one secondary follicle is selected in response to FSH and continues to grow and mature, both in terms of hormone production and egg maturation. As the granulosa cells proliferate, greater amounts of estrogens are produced and released. The granulosa cells also further differentiate into cumulus cells that surround the oocyte and mural cells that surround a fluid-filled antrum. Mural granulosa cells are important for steroidogenesis and ovulation, whereas cumulus granulosa cells

Fig. 1 Secretion of hormones during folliculogenesis and their effects on HPG axis. GnRH neurons excited by Kisspeptin neurons secrete GnRH. The GnRH stimulates FSH and LH secretion to activate folliculogenesis in ovaries. While primordial follicles are covered with a layer of pregranulosa cells before being stimulated, those are surrounded by a layer or multilayers of granulosa cells after being waken up. In the ovaries, immature primordial follicles are awakened by activation factors and grow until becoming antral follicles. As follicles grow, estradiol, AMH, activins, and inhibins are secreted. The AMH from growing follicles inhibits the activation of primordial follicles. Estradiol and inhibins from growing follicles and progesterone from corpus lutea have an effect of negative feedback on pituitary and GnRH neurons. The negative feedback signaling suppresses the excitatory signals from hypothalamus–pituitary to ovaries and shifts follicular to luteal phase, resulting in successful menstrual cycle.

support the growth and maturation of the oocyte. During antral follicle growth, FSH is critical for granulosa cell proliferation, estradiol production, and LH receptor expression (Richards, 1994).

Sex Steroids in Folliculogenesis

Estradiol is produced by granulosa cells of growing follicles in the ovary, starting at the late preantral stage; up to this point, production of estradiol is limited by insufficient androgen substrate for aromatization. Theca cells express key steroidogenic enzymes such as CYP11A1, HSD3B1, and CYP17A1, while granulosa cells contain CYP19A1. Once the theca cell layer forms, aromatizable androgen and its estradiol precursor, androstenedione, are produced in theca cells and transferred to granulosa cells for conversion to estradiol. As late preantral follicles continue to grow through the antral stages, the level of estradiol increases with proliferation of granulosa cells (Edson et al., 2009). Estradiol from granulosa cells plays a positive feedback role in the HPG axis, stimulating production of FSH in the pituitary that promotes further follicle growth and production of steroid hormones in the ovary. Estradiol may also have intrafollicular actions: administration of estradiol to hypophysectomized rats stimulated the proliferation of granulosa cells in small preantral follicles and reduced atresia. Studies indicate that a combination of FSH and estradiol or androgen aromatized to estradiol in vitro can stimulate granulosa cell proliferation. The estrogen receptor, ER β , is expressed in granulosa cells of growing follicles, while ER α is expressed in thecal and interstitial cells (Britt and Findlay, 2003). Based on the expression patterns of these receptors, ER β in granulosa cells is likely involved in ER-stimulated granulosa cell proliferation and follicle growth, decreasing follicle atresia, and increasing the number of oocytes released following ovulation induction.

During puberty, androgen blood levels increase in females and induce body changes during sexual maturation, mainly acting on the adrenal glands and ovaries. Androstenedione that is converted from dehydroepiandrosterone converts to testosterone, and testosterone converts to 5 α -dihydrotestosterone (DHT) (Lebbe and Woodruff, 2013). Among these androgens, testosterone and DHT are the only two hormones that bind and activate the androgen receptor (AR), which is localized in granulosa cells; stromal cells; theca cells in humans; and oocytes in rats, mice, and pigs. It has been shown that androgens induce follicle activation through AR in the granulosa cells in primates, suggesting that androgens, like estradiol through ER β , also boost the effect of FSH on growing

follicles (Weil et al., 1998). Testosterone stimulates the transition of primary to secondary follicles in a dose-dependent manner in the fetal bovine ovary, which is inhibited by the AR antagonist flutamide. A similar effect of androgens has also been reported in ovaries from testosterone-treated transsexual women.

Peptide Hormones in Folliculogenesis

In addition to sex steroid hormones, the ovary produces many peptides that work as autocrine, paracrine, or endocrine factors. Among these peptides, *activins*, *inhibins*, and *follicle-stimulating hormone* are produced by the granulosa cells. *Activins* are glycoprotein dimers composed of two subunits, βA and βB , which form activin A ($\beta A\beta A$), B ($\beta B\beta B$), or AB ($\beta A\beta B$) (Thompson et al., 2004). As autocrine and paracrine factors produced by granulosa cells, the activins are important in the development of early-stage follicles (Pangas and Woodruff, 2000). Activin A produced by granulosa cells of primary and secondary follicles and cumulus cells of antral follicles locally enhances FSH action on granulosa cells. In vitro assays have shown that activin and FSH signaling synergize to stimulate follicle growth and secretion of estradiol and inhibin. Activins from granulosa cells also inhibit androstenedione production by suppressing excess androgen biosynthesis in preantral and small antral follicles through modulation of LH signals (Makanji et al., 2014; Woodruff et al., 1988). Activin is also synthesized in the pituitary where it plays a role in regulating FSH production.

Inhibins are also glycoprotein dimers composed of a unique α -subunit and either the activin βA -subunit (inhibin A) or βB -subunit (inhibin B). During the human menstrual cycle, inhibin B is dominantly expressed in the early follicular phase, decreases in the midfollicular phase, and is undetectable after the LH surge in the luteal phase. Inhibin A is very low during the early follicular phase, increases gradually in the midfollicular phase, and peaks during the luteal phase (Woodruff and Mayo, 1990). As endocrine factors, ovarian inhibins play a very important feedback role of selectively inhibiting expression of the FSH β -subunit in the pituitary, thereby limiting FSH production.

Follicle-stimulating hormone is a peptide hormone that is mainly produced in the pituitary and the ovary and binds and neutralizes activin. In the pituitary, follicle-stimulating hormone plays an inhibitory role by reducing activin-stimulated FSH production (Michel et al., 1993).

Folliculogenesis is also negatively regulated by *anti-Müllerian hormone* (AMH), also known as Müllerian-inhibiting substance (Teixeira et al., 2001). AMH is a peptide growth factor belonging to the TGF- β family. It was discovered as the hormone produced by fetal testis at the time of Müllerian duct regression during development of male reproductive tissues. The ovaries of homozygous AMH-null female mice were found to contain no primordial follicles and a greater number of growing preantral follicles compared to wild-type mice (Durlinger et al., 1999). It was subsequently found that AMH is mainly secreted by granulosa cells of preantral follicles in mice and antral follicles in humans. AMHR2, an AMH type II receptor, is expressed in granulosa cells of primary and growing follicles. In both mice and humans, AMH negatively regulates initial follicular recruitment from the quiescent pool by exerting an inhibitory effect on the transition from primordial to primary follicles. AMH can be detected in serum, and because of its expression pattern in growing preantral follicles, it has become a measurement of the ovarian reserve and ovarian function. Because the levels of AMH in serum positively correlate with the size of the primordial follicle pool and AMH levels decline with age and ovarian dysfunction, AMH has been suggested as a clinical marker for predicting the age of menopause, assessing the ovarian reserve before assisted reproduction procedures, and predicting gonadal function after cancer treatment. AMH is a more sensitive marker for ovarian reserve compared to FSH, which has been used in clinical care as a standard biomarker of reproductive capacity.

Hormones at and After Ovulation

As the dominant antral follicle reaches its final stage, serum estradiol reaches its peak and secretion of pituitary FSH is suppressed. Pituitary LH production increases, eventually resulting in an LH surge that induces ovulation of the oocyte from the dominant antral follicle. As oocytes do not have LH receptors, cyclic AMP in granulosa cells is transported into oocytes through gap junctions when the LH surge occurs. The ovulated oocyte resumes meiosis while the cumulus granulosa cells left behind expand and terminally differentiate to form the corpus luteum (CL). The CL becomes a very important endocrine organ, as CL cells (10–20 mm) secrete high levels of progesterone and moderate amounts of estradiol. Progesterone from the CL acts on the lining of the uterus, increasing its thickness in preparation for implantation of the fertilized egg, and thus is critical to sustain early pregnancy. The size of the CL correlates with the production of serum progesterone during early pregnancy. The CL produces progesterone until the placenta begins to produce progesterone around 10 weeks gestation in human. If implantation does not occur, the CL undergoes atresia and progesterone production stops; in response, the lining of the uterus gradually stops thickening and menstruation begins.

Progesterone receptor (PR) is localized in theca cells of small antral follicles and granulosa cells of preovulatory follicles that are exposed to LH/human chorionic gonadotropin, or granulosa cells undergoing luteinization, in primate and rabbit ovaries (Hild-Petito et al., 1988). In the porcine and rat ovary, LH may induce PR mRNA expression in granulosa cells, and short-form PR-A is more abundant than the long-form PR-B. It has been shown that progesterone can enhance the activity of steroidogenic enzymes in granulosa cells and progesterone production by these cells (Fanjul et al., 1983). In rat granulosa cells, progesterone may enhance the response to FSH by increasing cAMP and inhibiting FSH-stimulated estradiol production.

Glossary

Cytochrome P450 A superfamily of > 220 genes that are grouped into 36 gene families that encode heme-based enzymes. Three of the enzymes that are required for estrogen biosynthesis (cholesterol side chain cleavage enzyme, 17-hydroxylase, and aromatase) are members of this superfamily.

Estrogen Female sex hormone (although also present in males) with steroid hormone structure.

Estrogen receptor-alpha and beta; GPR30, and ER-X *ER α* and *ER β* are about 66-kDa nuclear proteins that bind to estrogens with high affinities. The gene structures of *ER α* and *ER β* are similar, including N- and C-terminal activational domains, a hinge region, a nuclear binding domain, and a ligand binding domain. The nuclear ERs are ligand-regulated transcription factors. GPR30 is a membrane ER activated by 17 β -estradiol and it is involved in mediating fast estrogen responses via an interaction of second messenger systems. ER-X is also a membrane-associated ER activated primarily by 17 α -estradiol but it also binds 17 β -estradiol.

Estrogen response element A palindromic nucleotide sequence that is specifically recognized and bound by the DNA-binding domain of estrogen receptors. The consensus estrogen response element is GGTCAnnnTGACC.

Sex hormone binding globulin A glycoprotein found in the blood that binds some androgens and estrogens with relatively high affinities. This protein contributes to the regulation of the amount of free estrogen present in plasma.

Historical Background

The name “estrogen” comes from the observations more than 100 years ago when it was found that ovariectomy (castration of females) resulted in a number of changes in the reproductive tract and the ovaries transplanted back into ovariectomized animals ameliorated these effects. These observations indicated that the ovary produced a substance that acted in an endocrine manner, that is, it secreted the substance into the systemic circulation by which it reached the responsive organs/tissues. This conclusion was supported by the observations that reproductive organs, such as the vagina and uterus, underwent cyclical changes in a fashion similar to the ovaries. Because the substance produced by the ovaries induced estrus, it was referred to as estrogen (estrogen). The laboratories of Doisy and Butenandt (Doisy, 1972) crystallized a low-molecular-weight lipophilic steroidal substance from the urine of pregnant women which they originally termed “theelin” and later renamed it estrone. Many years of effort were dedicated to identify the mechanism by which estrogens stimulated the growth in reproductive tract tissues. A major discovery occurred in 1957 when Jensen reported that tritium-labeled estradiol was concentrated in uterine cells and induced growth without itself undergoing chemical changes. The subsequent demonstration that increasing amounts of the antiestrogen nafoxidine could inhibit uterine uptake of labeled estradiol as well as estrogen-stimulated cell growth corroborated that steroid binding to a bona fide receptor is required for estrogen action. The classic estrogen receptor (ER) (now called *ER α*) was discovered in 1985/1986 (Walter et al., 1985; Green et al., 1986) and the second ER (now called *ER β*) was discovered in 1996 (Kuiper et al., 1996).

Like other members of the superfamily, *ER α* and *ER β* are nuclear, ligand-activated transcription factors, although *ER α* is also associated with the cell membrane (*mER α*) (Levin, 2005; Zivadinovic and Watson, 2005).

In addition to the nuclear *ER α* and *ER β* , 17 β -estradiol also binds to membrane-associated ERs that are different from the nuclear *ER α* and *ER β* . Among these, the G-protein associated ER (GP-ER or GPR30) localizes to the endoplasmic reticulum and induces adenylate cyclase (AC), extracellular signal-related kinase (ERK), protein kinase A (PKA), protein kinase C (PKC), phosphoinositide 3-kinase (PI3K), and epidermal growth factor receptor (EGFR) signaling. GP-ER or GPR30 plays a role in the rapid non-genomic signaling events widely observed following stimulation of cells and tissues with estradiol (Prossnitz et al., 2007).

Another membrane-associated ER is called ER-X that is bound and activated by 17 α -estradiol and 17 β -estradiol. It shows sequence homology with *ER α* and *ER β* and activates the MAPK/ERK pathways (Toran-Allerand et al., 2002). The receptor is insensitive to the antiestrogen ICI-182,780 (fulvestrant).

Structural Features

Estrogens are steroid hormones. The estrane steroid nucleus, which is common to all estrogens and distinct from other classes of steroids such as androgens and progestins, contains 18-carbon atoms arranged into four rings as shown in Fig. 1A. The aromatic A ring with the phenolic hydroxyl group located at the C3 position and an oxygen atom in the form of a hydroxyl or ketone group at the C17 position are critical for the hormonal activity of all estrogens (see below).

Fig. 1 The steroid structure and estrogens. The estrane steroid nucleus, which is common to all estrogens and distinct from other classes of steroids such as androgens and progestins, contains 18-carbon atoms arranged into four rings. The aromatic A ring with the phenolic hydroxyl group located at the C3 position and an oxygen atom in the form of a hydroxyl or ketone group at the C17 position are critical for the hormonal activity of all estrogens (see below). (B) 17β-estradiol; note the aromatic (aliphatic) A ring, a –OH group at C3 and C17 positions. (C) estrone: note the lack of –OH at C17 position. (D) estriol: note the keto group at C20 position.

The most potent, naturally occurring estrogen is 17β-estradiol, which has 3-hydroxyl and 17β-hydroxyl groups (**Fig. 1B**). In humans, there are two other major forms of estrogen in the circulation, estrone (**Fig. 1C**) and estriol (**Fig. 1D**). In contrast to 17β-estradiol, estrone has a ketone group at the C17 position instead of a hydroxyl, and estriol differs from 17β-estradiol by the addition of a 16α-hydroxyl group. The biological activity of estrogens is determined in part by their ability to bind to and activate the estrogen receptors. 17β-Estradiol is the most active as an estrogen; estrone is about one-third as active as 17β-estradiol and estriol is about one-sixteenth as active as 17β-estradiol (Estradiol > Estrone > Estriol).

Biosynthesis of Estrogens

The vast majority of estrogens are synthesized by the ovarian follicles (**Fig. 2A,B**). In the cortex, just below the tunica albuginea of the ovary, the primordial follicles first appear in the third month of fetal development. Then, during each menstrual cycle, a dozen or two of these cells grow but only one or two completes fill maturation and becomes Graafian follicle. The growth and maturation

Fig. 2 The ovary. (A) The ovary and folliculogenesis. (B) The mature Graafian follicle. The granulosa cells around the egg (corona radiata) and around the antrum secrete estrogen and the theca cells around the granulosa cells secrete testosterone which diffuses to the granulosa cells. The granulosa cells convert testosterone to 17β-estradiol via the P450arom and release it into the general circulation. From Ross MH, Pawlina W (2006) Histology: A Text and Atlas (5th edn.). Lipincott Williams & Wilkins.

of these follicles is stimulated by gonadotropins from the anterior pituitary. During this process, the single layer of follicle cells gives rise to a stratified epithelium, the stratum granulosum. The granulosa cells are surrounded by theca cells (interna and externa) of stromal origin. In humans, luteinizing hormone (LH) stimulates the cells of the theca interna to secrete androgens, which serve as estrogen precursors. In response to follicle-stimulating hormone (FSH) from the anterior pituitary, the granulosa cells catalyze the conversion of androgens to estrogens, which in turn stimulate the granulosa cells to proliferate resulting in increased estrogen levels until the mid-cycle ovulation. After ovulation, the Graafian follicle becomes corpus luteum and secretes primarily progesterone but estrogens as well.

All steroid hormones originate from C27 cholesterol (Fig. 3). The main source of cholesterol required for the synthesis of steroid hormones (steroidogenesis) is LDL-cholesterol. Cholesterol is metabolized down to a number of enzymatic pathways and is converted to the 21-, 19-, and 18-carbon steroid hormones, respectively (Samavat and Kurzer, 2015).

Humans produce several different estrogens whose biosynthesis occurs in a variety of tissues and they are gender and age-dependent. In premenopausal women, 17 β -estradiol is the most abundant estrogen and the majority of this steroid is produced by the granulosa cells of the ovary (see above). Plasma 17 β -estradiol levels vary during menstrual cycle and the highest levels are found in the late follicular stage. Relatively high levels of estrone also are present in cycling women, but little originates in the ovary. Most estrone is generated by the aromatization of androstenedione in adipose tissue. Aromatase is present in skeletal muscle, skin, hair follicles, bone tissue, several sites in the brain, and the Leydig cells of the adult testes. During pregnancy, estriol, which is produced by the placental aromatization of fetal-derived androgens, is the most abundant estrogen and its levels are

Fig. 3 Biosynthesis of estrogens. All steroid hormones originate from C27 cholesterol. Estrogen biosynthesis requires three hem-based cytochrome P450 enzyme complexes and two different dehydrogenases. The rate-limiting step in all steroid synthesis is the removal of the cholesterol side chain by the cytochrome P450 side chain cleavage enzyme which results in the generation of the C21 steroid, pregnenolone. Subsequent processing by 17 α -hydroxylase cytochrome P450, which converts the steroid from a C21 to a C19 structure, and 3/3-hydroxysteroid dehydrogenase, which oxidizes the hydroxyl group at the C3 position to a ketone group, results in the synthesis of the C19 estrogen precursor, androstenedione. The cytochrome P450 aromatase enzyme (P450arom) then catalyzes the unsaturation and aromatization of the A ring to produce estrone. Then, 16 α -hydroxylase converts estrone to estriol. Androstenedione can also be converted to testosterone and then, testosterone is converted to 17 β -estradiol by the P450arom. Abbreviations: StAR: steroidogenic acute regulatory protein; CYP11A1: side-chain-cleavage of P450; CYP17A1: 17-hydroxylase/17,20-lyase; HSD3B2:3 β -hydroxysteroid dehydrogenase-delta5,4 isomerase type 2; CYP19A1: aromatase; HSD17B1: 17 β -hydroxysteroid dehydrogenase type 1. From Samavat H, Kurzer MS (2015) Estrogen metabolism and breast cancer. *Cancer Letters* 356, 231-243.

a marker of fetal/placental functions. In postmenopausal women and in men, relatively low levels of 17β -estradiol (< 20 pg/mL) are generated by the peripheral conversion of androgens to estrogens. The total amount of estrogens synthesized by extragonadal sites may be small, but the local tissue concentrations achieved are probably high and exert biological influence locally.

Estrogen biosynthesis requires three hem-based cytochrome P450 enzyme complexes and two different dehydrogenases. The rate-limiting step in all steroid synthesis is the removal of the cholesterol side chain by the cytochrome P450 side chain cleavage enzyme, which results in the generation of the C21 steroid, pregnenolone. Subsequent processing by 17α -hydroxylase cytochrome P450, which converts the steroid from a C21 to a C19 structure, and 3β -hydroxysteroid dehydrogenase, which oxidizes the hydroxyl group at the C3 position to a ketone group, results in the synthesis of the C19 estrogen precursor, androstenedione. The cytochrome P450 aromatase enzyme (P450arom) then catalyzes the unsaturation and aromatization of the A ring to produce estrone.

Both androstenedione and estrone are substrates for 17β -hydroxysteroid dehydrogenase (17β -HSD), which can reversibly convert these oxosteroids to their 17β -hydroxysteroid counterparts, testosterone and 17β -estradiol, respectively.

Most cells do not express the complete complement of steroid biosynthetic enzymes required to synthesize estrogens. Thus, the predominant C18 estrogen produced by a given tissue depends on the C19 steroid presented to the aromatase enzyme complex. For example, granulosa cells of the ovarian follicles lack 17α -hydroxylase activity and are, therefore, dependent on an external source for the C19 steroid necessary for estradiol biosynthesis. These precursors (androstendione and testosterone) are synthesized in the thecal cell layer of the ovarian follicle (Fig. 2) and then CYP450 aromatase convert them to estrogen and 17β -estradiol in the granulosa cells. The formation of estrone by adipose tissue utilizes androstenedione made in the adrenal cortex as its C19 precursor. Estriol is produced by the syncytiotrophoblasts within the placenta from 16α -hydroxydehydroisoandrosterone-sulfate produced by the combined activities of the fetal adrenal and liver.

Transport of Estrogens

After secretion into the circulation, only 2% or 3% of biosynthetic 17β -estradiol remains free in plasma. Of the remaining amount, approximately 60% is weakly bound to albumin and 38% is bound to a 95 kDa glycoprotein, sex hormone-binding globulin (SHBG). SHBG binds both estrogens and androgens. Its binding affinity to androgens (testosterone and dihydrotestosterone) is approximately five- and three-fold greater, respectively, than to 17β -estradiol. The protein-bound hormone is inactive, and that only the free fraction is able to enter target cells and exert biological effects. The metabolic clearance rate of estrogens is inversely related to their affinity for SHBG and other plasma-binding proteins. The concentration of SHBG, therefore, influences estrogen metabolism and the amount of hormone available for entry to the target cell. Plasma SHBG levels are affected by a number of clinical conditions including pregnancy, diabetes, obesity, and sex. SHBG levels are two-fold higher in women than men.

Metabolism of Estrogens

Circulating estrogens are quickly metabolized in the liver to inactive, water-soluble compounds which are then excreted in the urine and feces. The vast majority of estrogen end up in the urine as glucuronosides. A second major class of catabolic products is the catechol estrogens (they have catecholaminergic and estrogenic activities) and are primarily 2-hydroxyestrogens (Samavat and Kurzer, 2015) (Fig. 4). Some catechol estrogens (e.g., 3-hydroxy estrone) by interacting with ER and the noradrenergic, dopaminergic and serotonergic pathways in the CNS may modulate behavior (cognition, memory) and may play a role in CNS diseases such as Alzheimer's disease.

Mechanism of Estrogen Action

Estrogens are lipophilic substances and it is believed that they passively diffuse across the plasma membrane and then bind to high-affinity receptor proteins, known as ERs. The ERs ($ER\alpha$ and $ER\beta$) are members of the nuclear receptor superfamily (Walter et al., 1985; Green et al., 1986; Kuiper et al., 1996), which includes receptors for other steroids (e.g., progesterone and androgens), vitamins (e.g., vitamin D and vitamin A (retinoids)), and thyroid hormone. Like other members of the superfamily, the ERs are nuclear, ligand-activated transcription factors, although $ER\alpha$ also associated with the membrane. After entering the cell through the plasma membrane, estrogen binds to ERs in the nucleus. In the nucleus, ERs are present as inactive monomers bound to heat-shock proteins. Upon binding to estrogen ERs dissociate from the heat-shock protein. This causes receptor dimerization which increases the affinity and the rate of receptor binding to estrogen response element (ERE) in the promoter of estrogen-regulated genes. In addition, the activated ERs bind to a number of nuclear proteins that act as bridging factors between the ERs and the general transcriptional machinery. By this complex mechanism, estrogens regulate the expression of target genes. The regulation can be stimulation or repression. The changes in the expression of these genes and the proteins that they encode result in an estrogenic response within a given target cell.

Estrogen may also bind to G-protein associated ER (GP-ER or GPR30) and induces AC, ERK, PKA, PKC, PI3K, and EGFR signaling (Zivadinovic et al., 2005; Prossnitz et al., 2007). This protein is a member of the rhodopsin-like family of G-protein-coupled receptors and is a multi-pass membrane protein that unlike the other members of the GPCR family localizes to the

Fig. 5 Conjugates of estrogens: estradiol benzoate, estradiol valerate, estrone sulfate and estradiol valerate.

cyclopentylpropionate (**Fig. 5**). De-esterification of these compounds via esterases in the liver produces biologically active 17β -estradiol in vivo which then reaches all ERs in the body.

Brain-selective bioprecursor approach

As estrogens beside their many beneficial effects (see below) also have unwanted effects in the periphery (overstimulation of the uterus leading to spotting or bleeding or even cancer; stimulation of breast and potentially causing cancer; elevated coagulation; etc.) efforts have been devoted to develop brain-selective estrogens which would be beneficial in preventing/treating menopausal hot flushes, cognitive and memory declines, depression, sleep fragmentation, reduced sexual desire, etc.)

Recently published studies ([Prokai et al., 2015](#)) have identified $10\beta,17\beta$ -dihydroxyestra-1,4-dien-3-one (DHED) as a brain-selective bioprecursor prodrug for the potential treatment of estrogen-responsive diseases of the central nervous system. While typical prodrugs rely on the attachment of hydrolysis-sensitive “pro-moieties” to overcome caveats associated with the use of the parent agents (see above), DHED is actually a bioprecursor prodrug produced by a bioreversible chemical modification (i.e., a stereo-selective oxidation and without the use of an auxiliary pro-moiety) of 17β -estradiol (**Fig. 6**). As prodrugs, DHED completely lacks the biological activities of estrogens and other steroid hormones, until it is metabolized to 17β -estradiol (as shown in **Fig. 1**). Since DHED is orally bioavailable and is converted to 17β -estradiol only in the brain and not in the periphery, once it is developed for human use, it could be a safe estrogen therapy to treat menopausal symptoms (see above) without stimulating the uterus and the breast or increasing the chance of coagulation in the blood. Moreover, DHED could be used for men as well. Men going through the natural andropause or castrated because of hormone-sensitive prostate cancer have similar symptoms as menopausal women. The similarity of the symptoms in both sexes indicates that most of these symptoms are due to a common cause; that is, the lack of estrogen (primarily 17β -estradiol) action in the brain. The lack of 17β -estradiol is obvious in menopausal women; however, it does not seem to be obvious in men because 17β -estradiol is considered primarily a feminine steroid hormone. On the other hand, 17β -estradiol is well distributed in males’ brain due to its conversion from testosterone through the actions of aromatase ([MacLusky et al., 1987](#)). Indeed, estrogens (e.g., ethinyl estradiol and diethylstilbestrol (see below) (**Fig. 7**) have been successfully used in men receiving androgen depletion therapy for the alleviation of hot flushes, cognitive deficits and depression/anxiety associated with the hypoandrogenic conditions (for reviews, see ([Gillies and McArthur, 2010](#))). Select studies have suggested that 17β -estradiol has antidepressant-like and anxiolytic-like effects in males as well. Furthermore, although testosterone itself has clear effects on behavior, its mood- and anxiety-related actions might also be mediated through aromatase action and ERs ([Frye et al., 2008](#)). Except for hot flushes, the above neurological and psychiatric symptoms may be treated or prevented with medications other

Fig. 7 Synthetic estrogens: ethinyl estradiol and diethylstilbestrol.

than estrogens. However, only estrogens can provide full relieve from hot flushes based on current clinical practices. Therefore, current preclinical studies support the notion that DHED could be a safe therapy not only in women but in men as well.

Synthetic, non-steroidal estrogens: 17 α -ethinyl estradiol (EE) and diethylstilbestrol (DES)

17 α -ethinyl estradiol (EE) has an ethinyl group linked to C17 of the estradiol molecule (Fig. 7). This compound is the most widely used synthetic oral estrogen and is the estrogen component found in most oral contraceptives.

Another synthetic, nonsteroidal compound which mimics estrogen-like effects is diethylstilbestrol (DES; Fig. 7), which was generated for clinical use. Diethylstilbestrol binds to the ER with high affinity yet does not bind to the plasma transport protein, sex hormone-binding globulin (see Section **Transport of Estrogens**), and is therefore a more potent estrogen than 17 β -estradiol.

In addition, there are a variety of chemicals found in the environment that possess weak estrogenic activity; they are referred to as “xenoestrogens.” This group of compounds includes a variety of industrial products, including pesticides such as DDT and other organochlorine compounds (e.g., polychlorinated bisphenols) as well as the monomer used to produce polycarbonate plastics, bisphenol A. Many of these molecules have a phenolic ring structure and hydroxyl groups that contribute to their ability to bind to the ER with moderate affinity. Although the impact of these molecules on human health is controversial, these chemicals are able to mimic estrogen effects in laboratory tests and several have been shown to disrupt reproductive processes in wildlife, suggesting that they may impinge on estrogen signaling pathways in nature.

It is worth noting that antiestrogens also have been developed for clinical uses, such as the treatment of breast cancer. However, today the most promising therapy for ER-positive breast cancer is the use of aromatase inhibitors which block the formation of estrogens from androgens.

Conjugated equine estrogens

A unique approach of estrogen therapy is the use of conjugated equine alone for estrogen replacement therapy or in combination with progestins as hormone replacement therapy. PREMARIN (pregnant mare urine; Fig. 5) contains primarily estrone, equilin, equilinenin as water soluble sodium sulfate conjugates. At least 10 other active estrogenic products are in the mixture including 17 α -dihydroequilin sulfate, 17 α -dihydro-equilin sulfate and 17 α -estradiol sulfate.

Selective estrogen receptor modulators (SERMS)

SERMS are a class of drugs that have features that can act estrogen receptor agonist and an antagonist, depending on the target tissue and include tamoxifene, raloxifene, nafoxidine, toremifene, and bazedoxifene (Fig. 8). SERMS are now being used as a treatment of breast cancer, osteoporosis, and postmenopausal symptoms.

Natural estrogens

In addition to men-made xenoestrogens discussed above, there are a number of naturally occurring substances that exhibit estrogenic activity. These chemicals are produced by plants and are more specifically referred to as phytoestrogens. The most abundant phytoestrogen is genistein, which is found in high concentration in soybeans. Diadzein (Fig. 9), S-equol (Fig. 9), coumestrol, resveratrol, quercetin, etc. also belong to this group. Phytoestrogens have weaker estrogenic activity compared to 17 β -estradiol or estrone. As other estrogens, they can bind sex hormone binding proteins. Dietary phytoestrogens are metabolized by intestinal bacteria,

absorbed, conjugated in the liver by sulfotransferases and UDP-glucuronyl transferases, circulated in plasma, and excreted in urine. Phytoestrogens can bind to the ERs with varying degrees of effectiveness. However, the mechanism by which they exert their estrogenic effects in vivo is a matter of ongoing investigation.

Progesterone Signaling in the Endometrium

Juanmahel Dávila, Indrani C Bagchi, and Milan K Bagchi, University of Illinois at Urbana-Champaign, Urbana, IL, United States

Introduction

For more than a century, it is known that corpus luteum (CL) and its secretions are critical for endometrial function and pregnancy. In 1903, it was demonstrated that the removal of the corpora lutea of rabbits during early pregnancy resulted in pregnancy loss (Vaisbuch et al., 2015). Decades later, it was shown that injection of CL extracts into ovariectomized pregnant rabbits could sustain normal implantation as well as embryo survival and growth (Lessey, 2011; Vaisbuch et al., 2015). It was proposed that the biological effects of the CL extracts are due to the hormone “progestin” (Vaisbuch et al., 2015). By the mid-1930s, four different research groups reported the purification and characterization of progesterone (P), a steroid hormone derived from cholesterol (Lessey, 2011; Vaisbuch et al., 2015).

A large body of work has established that P is a critical regulator of normal female reproductive functions. It elicits a broad spectrum of responses in tissues, such as the ovary, uterus and mammary gland (Graham and Clarke, 1997). These include ovulation, proliferation and differentiation of the uterine tissue during pregnancy, lobuloalveolar development in the mammary gland, and orchestration of the menstrual cycle (Conneely et al., 2001; Kim et al., 2009; Vaisbuch et al., 2015). Besides its role in the reproductive tissues, P also influences the functions of the anterior pituitary, ventromedial hypothalamus, and preoptic areas. In the mouse brain, it elicits signals that are required for the regulation of the female sexual receptivity response (Conneely et al., 2001; Graham and Clarke, 1997; Vaisbuch et al., 2015). Lastly, there is emerging evidence of P action in diverse other tissues, such as the bone, lung, adipose tissue, kidney, and immune system (Al-Sabbagh et al., 2012; Graham and Clarke, 1997; Vaisbuch et al., 2015).

Progesterone produced by the ovary plays a critical role in regulating many biologically distinct processes that are associated with the establishment and maintenance of pregnancy. In the ovary, P signaling is implicated in ovulation and luteinization. In rodents, prior to ovulation, a surge of the luteinizing hormone stimulates a transient expression of the progesterone receptor (PGR) in granulosa cells of the preovulatory follicles (Conneely et al., 2001). The ovarian P then signals via the PGR to promote the expression of downstream molecular pathways that mediate the ovulatory process, culminating in the rupture of the follicle to yield the mature oocyte (Conneely et al., 2001; Kim et al., 2009). In humans, P secreted by the CL, which is formed following ovulation, dominates the secretory phase of the menstrual cycle. P signaling also exerts profound effects on mammary gland development during pregnancy in preparation for lactation (Conneely et al., 2001; Graham and Clarke, 1997). Although P has many roles in diverse tissues and cell types, this chapter will focus on the effects of this hormone on endometrial functions.

Structure and Function of the Progesterone Receptors

In target tissues, the cellular actions of P are mediated by its intracellular progesterone receptors (PGR). The PGR protein, which is a ligand-inducible transcription factor, was purified from the chick oviduct and human uterus (Graham and Clarke, 1997; Kaya et al., 2015; O'Malley, 2005; Vaisbuch et al., 2015). The cloning of the *PGR* gene, which is conserved among the vertebrate species, including humans and rodents, revealed that it belongs to the nuclear receptor superfamily (Conneely et al., 2001; O'Malley, 2005). A common feature of PGR and other members of this superfamily is a modular structure harboring distinct functional domains that allow them to function as ligand-inducible transcription factors (Al-Sabbagh et al., 2012; Binder et al., 2015; Vaisbuch et al., 2015). Accordingly, PGR has multiple distinct functional domains: an amino-terminal domain (A/B) harboring a transactivation function AF-1, a centrally located DNA binding domain (C), a hinge region (D), and a ligand binding domain (E) containing a second transactivation function AF-2 (Fig. 1). Moreover, like all other steroid receptors, PGR harbors signature amino acid motifs that serve as nuclear import and export signals, enabling the receptor to shuttle actively between the nuclear and cytoplasmic compartments (Al-Sabbagh et al., 2012; Binder et al., 2015; Vaisbuch et al., 2015).

The gene encoding human PGR is located on chromosome 11q22.1 and has eight exons (Al-Sabbagh et al., 2012; Binder et al., 2015; Conneely et al., 2001; Vaisbuch et al., 2015). There are two isoforms of human PGR, PGR-A (94 kDa) and PGR-B (114 kDa). These proteins are generated from alternate transcripts arising from a single *PGR* gene via different promoter usage. Both isoforms have the same DNA binding and ligand binding domains, but PGR-B possesses an additional transactivation domain AF-3 in the amino-terminal region (Fig. 1) (Binder et al., 2015; Graham and Clarke, 1997; Kaya et al., 2015; Li and O'Malley, 2003; Vaisbuch et al., 2015; Young, 2013). The presence of this additional transactivation domain in PGR-B allows it to interact with adjacent PGR-B dimers, different transcription factors, and coregulatory factors, which helps explain why PGR-B is a stronger transcriptional activator than PGR-A (Binder et al., 2015; Li and O'Malley, 2003; Patel et al., 2015; Vaisbuch et al., 2015).

The PGR isoforms are expressed at different levels in progesterone-responsive tissues, depending on developmental stage, hormonal status, or disease (Conneely et al., 2001; Graham and Clarke, 1997). The biological significance of the ratios of PGR expression is still unclear. However, the functional differences between the two PGR isoforms suggest that their differential expression may be critical for the appropriate cellular responses to P (Conneely et al., 2001). Notably, several additional alternatively

Fig. 1 Progesterone receptor (PGR) gene and its protein isoforms. (B) The primary mRNA transcripts derived from different transcription start sites. (C) Structural organization of the PGR-B and PGR-A proteins. Both PGR-B and PGR-A contain a transcriptional activation function AF-1 in the N-terminal domain (A/B) and a transcriptional activation function AF-2 in the C-terminal domain (E). PGR-B isoform contains an additional transcriptional activation function AF-3. The DNA binding domain (C), the hinge (D), and the ligand-binding domain (E) are shown.

transcribed, translated or spliced PGR variants have also been described in the literature, but their relevance and potential biological role remains controversial and will not be discussed in this chapter.

Genomic Actions of Progesterone Receptors

In PGR-expressing cells, the unliganded receptor exists in a large, multi-protein complex containing various heat shock proteins (e.g., HSP90, HSP70, and p23) and immunophilins (e.g., FKBP51 and FKBP52), which maintain the receptor in a transcriptionally inactive state (Fig. 2) (Al-Sabbagh et al., 2012; Vaisbuch et al., 2015). P, which is lipophilic, passively diffuses through the plasma membrane and binds to the intracellular PGR. Binding of P induces a change in the conformation of PGR that results in its dissociation from the chaperone proteins, dimerization, and translocation into the nucleus. The hormone-occupied PGR then binds to target genes via direct interaction with discrete DNA response elements, known as progesterone response elements (PREs) or via tethering interactions with other transcription factors (Conneely et al., 2001; Vaisbuch et al., 2015). The target gene-bound PGR recruits specific coactivator proteins and general transcription factors to form a productive transcription initiation complex to activate or repress RNA synthesis (Al-Sabbagh et al., 2012; Conneely et al., 2001; Patel et al., 2015; Vaisbuch et al., 2015).

Both PGR isoforms are capable of binding P and interacting with PREs and the transcriptional machinery to regulate gene expression (Conneely et al., 2001; Graham and Clarke, 1997; Patel et al., 2015). In target cells, these isoforms can potentially form three types of dimers: A:A homodimer, B:B homodimer, and A:B heterodimer. The specific contribution of each of these dimer species in mediating the regulatory effects of P depends on their differential transactivation properties. Several lines of evidence have suggested that PGR-A and PGR-B proteins are functionally distinct. When expressed individually in cultured cells, they display different transactivation properties that are specific to both cell type and target gene promoter used (Conneely et al., 2001). Studies have shown that PGR-A acts as a trans-repressor of PGR-B and other steroid receptors in certain cell and promoter contexts, presumably through competition for common limiting coactivators (Binder et al., 2015; Conneely et al., 2001; Li and O'Malley, 2003; O'Malley, 2005; Vaisbuch et al., 2015). Therefore, the ratios of the isoforms within a target cell under specific physiological conditions would likely alter the relative complement of dimeric complexes and exert a significant impact on the overall cellular responses to P (Conneely et al., 2001).

Modulation of Progesterone Receptor Activity by Co-regulatory Factors

It is well documented that the activity of nuclear PGR, as well as other nuclear steroid receptors, is regulated not only by the cognate hormone itself, but also by its interaction with co-regulatory factors, such as coactivators, corepressors, and chromatin modifiers (Al-Sabbagh et al., 2012; Binder et al., 2015; Vaisbuch et al., 2015; Young, 2013). Prominent among these factors are the three members of the steroid receptor coactivator (p160/SRC) family: SRC1, SRC2, and SRC3 (Binder et al., 2015; Vaisbuch et al., 2015). The SRCs, which share a high degree of sequence homology, harbor several LXXLL signature motifs that interact directly with the ligand-binding domain of the steroid receptors (Binder et al., 2015; Vaisbuch et al., 2015; Young, 2013). Binding of

Fig. 2 Progesterone enters the target cell via passive diffusion, binds to the intracellular progesterone receptor (PGR), which then translocates to the nucleus and initiates a series of genomic events that result in altered gene expression and cellular function. Binding of the hormone to the membrane-bound progesterone receptor (mPR) mediates non-genomic mechanisms.

SRCs to PGR creates a surface that recruits additional coactivator molecules, such as the coactivator-associated arginine methyltransferase-1 (CARM1), cAMP responsive element binding protein (CREB)-binding protein (CBP), and the related protein p300 (Al-Sabbagh et al., 2012; Binder et al., 2015; Li and O'Malley, 2003). The resulting multimeric coactivator protein complex then controls transcription by modulating local chromatin structure via histone acetylation/methylation. The SRCs also harbor a bHLH-PAS motif within the amino-terminal region, which can interact with other transcription factors binding to nearby genomic sites. Besides interacting with the SRCs, PGR is also able to recruit other multiprotein complexes, such as the SWI/SNF chromatin remodeler, mediator complex, or proteasomes to dynamically mediate and coordinate the processes necessary to accomplish transcription of PGR target genes (Al-Sabbagh et al., 2012; Binder et al., 2015; Li and O'Malley, 2003).

In cell-based assays, all three members of the SRC family enhance PGR-mediated gene activation. Knockout mouse studies, however, have revealed that these coactivators play tissue-specific roles *in vivo*. Whereas SRC-1 regulates steroid hormone sensitivity in the uterus, SRC-3 controls mammary gland development. SRC-2 plays a critical role in both organs (Vaisbuch et al., 2015). The SRC-2 knockout mice manifested a deficient uterine decidual response to P stimulation and an early block in embryo implantation (Vaisbuch et al., 2015; Young, 2013). Ablation of SRC-2 also suppresses P-induced ductal side branching and alveologenesis in the mammary gland. Collectively, these data substantiate the importance of SRCs in regulating the biological actions of P.

Non-Genomic Actions of Progesterone

During the past several years, a growing body of literature supports the concept that P activates a variety of rapid signaling events, independent of its role as a nuclear receptor (Moussatche and Lyons, 2012; Pru and Clark, 2013). This mode of signaling involves the activation of signal transduction cascades that generate intracellular second messengers and changes in Ca^{2+} ion flux. Additionally, this mode of PGR signaling has been shown to activate intracellular kinases, including the cAMP-dependent protein kinase A, the cyclin-dependent kinase-2, the mitogen activating protein kinase (MAPK), and the stress-activated p38 MAPK (Fig. 2) (Moussatche and Lyons, 2012; Pru and Clark, 2013; Vaisbuch et al., 2015). Non-genomic signaling is thought to be mediated by membrane-bound PGRs (mPRs), which have been identified in reproductive tissues, immune cells, the nervous system, and cancer cells (Moussatche and Lyons, 2012). Two families of non-classical membrane receptors have been identified, including the progestin and adipoQ receptor (PAQR) and progesterone receptor membrane component (PGRMC) (Pru and Clark, 2013). Members of the PAQR family with P binding activity belong to the G protein-coupled receptor superfamily and include mPR α , mPR β , and mPR γ (Pru and Clark, 2013; Valadez-Cosmes et al., 2016). Recent studies have reported that, in the myometrial cells

of pregnant humans, mPR α and mPR β are directly coupled to G-inhibitory proteins and may play a role in facilitating myometrial contractions (Vaisbuch et al., 2015). However, whereas the genomic actions are relatively well defined, in-depth mechanistic insights into non-genomic P actions are still needed, and therefore this mode of P-signaling will not be the focus of this chapter.

Progesterone Receptor-Mediated Signaling in the Endometrium

Lessons from the PGR Knockout Mouse Models

The development of a genetically engineered mouse model lacking PGR established that this receptor is essential for female fertility (Conneely et al., 2001; Lydon et al., 1995). Female mice lacking both PGR-A and PGR-B exhibit pleiotropic reproductive abnormalities including an inability to ovulate, uterine hyperplasia and inflammation, and defects in uterine receptivity and implantation. Analysis of their uteri revealed impaired decidualization and a hypertrophied epithelium that is non-functional for embryo implantation. Creation of knockout mice in which PGR-A expression, but not that of PGR-B, was selectively ablated resulted in a uterine phenotype similar to that exhibited by the PGR-null mice. In contrast, mice that lacked uterine PGR-B expression, but retained PGR-A, displayed no obvious uterine phenotypic defects. Collectively, these data indicated that PGR-A is the major isoform that mediates P-dependent uterine functions in the mouse. However, as described below, in the human, PGR-B seems to play a predominant role in controlling endometrial functions, particularly decidualization.

Role of PGR in Regulating Stromal-Epithelial Crosstalk

Successful implantation requires a receptive endometrium, which arises from a synchronized dialogue between epithelial and stromal cells in this tissue (Cakmak and Taylor, 2011; Conneely et al., 2001; Lessey, 2011). P plays a central role in directing this crosstalk that dictates endometrial cell proliferation and differentiation during early pregnancy. P-dependent pathways modulate the functions of endometrial epithelial and stromal cells creating an environment necessary for the establishment of pregnancy. Various mechanisms have been proposed to explain how P acts via PGR to (1) arrest epithelial proliferation, a necessity for the acquisition of uterine receptivity, and (2) stimulate stromal cell proliferation and differentiation, a requirement for the establishment of pregnancy.

17 β -estradiol (E2) stimulates uterine growth by inducing epithelial cell proliferation in the pro-estrous and estrous stages of the reproductive cycle in rodents or the proliferative phase of the menstrual cycle in humans (Binder et al., 2015; Conneely et al., 2001; Patel et al., 2015; Young, 2013). The postovulatory surge of P triggers the arrest of E2-dependent epithelial cell proliferation, followed by the transformation of the stromal cells into decidual cells, which secrete many factors that promote endometrial neoangiogenesis and guide recruitment of various immune cells to the pregnant uterus (Al-Sabbagh et al., 2012; Binder et al., 2015). The expression of the transcription factor Heart and Neural Crest Derivatives Expressed 2 (HAND2) in uterine stroma plays a central role in mediating the suppressive effects of P on epithelial proliferation (Li et al., 2011). During the receptive phase, P induces HAND2 expression in uterine stromal cells by directly interacting with the PREs in the *Hand2* promoter (Li et al., 2011; Kaya et al., 2015). HAND2 then suppresses the production of several fibroblast growth factors (FGFs), which act as paracrine mediators of mitogenic effects of E2 on uterine epithelium (Li et al., 2011). When the *Hand2* gene was deleted in the uterine stroma in a conditional knockout mouse model, persistent activation of the FGF receptor and the downstream ERK1/2 pathway was evident in the luminal epithelium, creating a non-receptive endometrium and leading to implantation failure. These findings unveiled a critical role for P-induced HAND2 in controlling epithelial function and uterine receptivity.

Another plausible mechanism by which P controls E2-induced epithelial proliferation and uterine receptivity is by inducing the epithelial expression of Kruppel-like transcription factor 15 (KLF15), which opposes the action of the Kruppel-like transcription factor 4 (KLF4) in the preimplantation uterus (Bhurke et al., 2016). E2 promotes epithelial expression of KLF4, which stimulates synthesis of the minichromosome maintenance (MCM)-2 protein, an essential component of the DNA synthesis machinery (Bhurke et al., 2016). P-induced KLF15 disrupts the transcriptional function of KLF4, suppressing the level of MCM-2 and thereby causing the cessation of E2-dependent epithelial proliferation.

The PGR-mediated expression of the morphogen Indian hedgehog (IHH) in uterine luminal epithelium has also been implicated in the promotion of uterine receptivity at the time of implantation. Transient epithelial production of IHH is a paracrine signal that induces the expression of its receptor, Patched (PTCH), in uterine stromal cells. The IHH then acts via PTCH to elevate the expression of the transcription factor COUP-TFII, which controls stromal cell proliferation and differentiation (Bhurke et al., 2016). Uteri of mice harboring a conditional deletion of *Ihh* fail to attain the receptive state, indicating that PGR-induced IHH production plays an important role during implantation by controlling the epithelial-stromal crosstalk.

Role of Progesterone Receptor in Decidualization

The most well-known reproductive role of P is to trigger the differentiation process in the stromal compartment, known as “decidualization,” which is characterized by the transformation of endometrial stromal cells into specialized secretory decidual cells (Al-Sabbagh et al., 2012).

One of the key P-regulated factors that control uterine decidualization is the bone morphogenetic protein 2 (BMP2), a member of the TGF- β superfamily. Decidual stage-specific expression of BMP2, which acts via its receptor on the uterine stromal cells during

early pregnancy, is critical for implantation and decidualization (Bhurke et al., 2016). Conditional deletion of the BMP2 gene in the uterus led to female infertility, primarily due to a failure of decidualization. Consistent with this finding, in vitro experiments showed that addition of BMP2 to undifferentiated mouse or human endometrial stromal cells markedly advanced their differentiation into decidual cells (Bhurke et al., 2016). Conversely, siRNA-mediated knockdown of BMP2 expression in these cells efficiently blocked the differentiation process (Bhurke et al., 2016).

The mechanism of action of BMP2 in the uterus is linked to the induction of the signaling molecule WNT4. BMP2 and WNT4 proteins exhibit overlapping spatiotemporal expression in mouse decidua in vivo. Addition of BMP2 robustly induces *Wnt4* transcripts in the primary mouse endometrial stromal cultures (Bhurke et al., 2016), giving rise to the view that BMP2 induces WNT4 expression to regulate stromal decidualization (Bhurke et al., 2016). Consistent with this view, conditional loss of *Wnt4* in mouse uterus impaired decidualization and led to implantation failure. BMP2 and WNT4 are also strongly induced in human endometrial stromal cells during decidualization. siRNA-mediated attenuation of their expression in these cells showed that both BMP2 and WNT4 are critical for this differentiation process. Chromatin immunoprecipitation (ChIP)-sequencing analysis revealed the existence of PREs directly targeted by both PGR-A and PGR-B in the *BMP2* gene (Kaya et al., 2015). Collectively, these results established that the BMP2-WNT4 pathway, operating downstream of PGR signaling, critically controls decidualization (Bhurke et al., 2016).

It was recently reported that BMP2 signaling through the BMP type 1 receptor on endometrial stromal cells promotes the expression of the transcription factor C/EBP β during decidualization (Bhurke et al., 2016). A global knockout of C/EBP β in mice displayed marked impairment in stromal cell proliferation and differentiation and female infertility, indicating a critical role of this factor in the regulation of decidualization (Bhurke et al., 2016). Further analysis revealed that, in C/EBP β -null uteri, stromal proliferation is blocked at G2 to M transition (Bhurke et al., 2016). Interestingly, ChIP analysis in human endometrial stromal cells showed that PGR interacts with C/EBP β at the P-regulated region of *AURKA*, which encodes the aurora kinase A, which is involved in microtubule formation and/or stabilization at the spindle pole during cell division (Kaya et al., 2015). These results are consistent with the view that C/EBP β and PGR act in concert to regulate human endometrial proliferation and differentiation.

PGR-dependent pathways also regulate the expression of the homeobox gene *Hoxa10* in mouse uterine stromal cells during decidualization. The *Hoxa10*-null mice exhibit a severe defect in decidualization and female infertility (Bhurke et al., 2016). The steroid receptor chaperon protein FKBP52 is a downstream target of HOXA10. Mice lacking FKBP52 also displays implantation and decidualization defects, phenocopying *Hoxa10*-deficiency (Bhurke et al., 2016). HOXA10 is also induced during human endometrial stromal cell differentiation in response to P. Genomic analysis identified PREs in the *HOXA10* gene promoter, indicating that direct regulation of *HOXA10* by PGR controls decidualization (Kaya et al., 2015).

Role of Progesterone Receptor in Human Endometrium

In the human, cyclic patterns of the ovarian E2 and P secretion produce changes in the endometrium that are responsible for the menstrual rhythm. The endometrium undergoes cyclic proliferative and secretory phases and exhibits only a short period of receptivity to embryo implantation in the mid-secretory phase of the cycle (Cakmak and Taylor, 2011). Within this time window, which lasts for a few days following ovulation, the endometrium becomes competent to implant the embryo to initiate a potential pregnancy (Cakmak and Taylor, 2011). P is critical to endometrial receptivity and functions to turn the E2-primed endometrium into a secretory tissue that promotes embryo survival and implantation (Lessey, 2011). The expression of PGR-A and PGR-B increases in all cell types during the proliferative phase (Binder et al., 2015; Patel et al., 2015). In the secretory phase, as serum P levels increase, PGR levels are maintained in the stroma and myometrium but decrease sharply in the glandular epithelium (Binder et al., 2015).

In the presence of high levels of P in the secretory phase, the stromal cells in human endometrium undergo a differentiation process known as pre-decidualization. If pregnancy is established, it triggers a more robust differentiation process that results in the formation of the decidual tissue. Both PGR isoforms, PGR-A and PGR-B, are expressed during decidualization (Kaya et al., 2015; Vaisbuch et al., 2015). Recent work demonstrated that PGR-B controls a substantially larger cistrome and transcriptome than PGR-A during human endometrial decidualization (Kaya et al., 2015). There is also evidence that PGR-B directly regulates the expression of PGR-A. Furthermore, the study found that PGR-A and PGR-B regulate overlapping as well as distinct sets of genes, many of which are known to play critical roles in decidualization and establishment of pregnancy in the mouse (Kaya et al., 2015). When PGR-A and PGR-B were co-expressed during human endometrial stromal cell differentiation, PGR-B played a predominant role, although both isoforms influence each other's transcriptional activity (Kaya et al., 2015; Vaisbuch et al., 2015). PGR-A and PGR-B also interact with transcription factors, such as FOS, JUN, CEBP β , and STAT3, which bind to neighboring genomic sites and modulate their transcriptional activities (Bhurke et al., 2016). Collectively, these interactions regulate the expression of many P-target genes that function in concert to properly control epithelial proliferation, stromal differentiation, angiogenesis, and immune response in the endometrium to render it receptive for implantation.

Perspectives and Future Directions

In normal endometrial cells, the hormone-occupied PGR acts in concert with cell-specific transcription factors and co-regulators to modulate chromatin structure and gene expression, which in turn control cell proliferation and promote differentiation. Analysis of the profiles of PGR occupancy at genomic sites and that of downstream gene expression during endometrial differentiation have offered a better understanding of the role of this receptor in uterine biology. These studies have revealed that several

PGR-regulated pathways profoundly influence endometrial functions, such as decidualization and angiogenesis, during pregnancy and these are often conserved in species ranging from the rodents to humans. Reduced P sensitivity and consequent disruptions in PGR signaling contribute not only to recurrent miscarriage and infertility but also to other reproductive pathologies, such as endometriosis (Bhurke et al., 2016). Endometriosis, a prevalent gynecological disease, is associated with dysregulation of a subset of P-dependent genes in the secretory endometrium, leading to the concept that it is a disease with underlying P resistance, perhaps arising from epigenetic alterations at PGR target loci in the genome. Further refinement of cellular and mouse models using CRISPR/Cas9 gene editing and continued analysis of a wide range of endometrial specimens obtained from human subjects suffering from infertility or endometriosis will provide a comprehensive molecular understanding of the genetic and epigenetic alterations that lead to dysregulation of PGR-regulated pathways in these disease conditions.

Androgens

Carlos Stocco, University of Illinois College of Medicine, Chicago, IL, United States

Introduction

For decades, *in vitro* studies have consistently demonstrated that androgens participate in the regulation of follicle growth and modulate gonadotropin action in the ovary. Conversely, clinical or biochemical evidence of androgen excess is one of the main criteria for the diagnosis of polycystic ovarian syndrome (PCOS), a disease that significantly decreases fertility. Androgens actions are mediated by the androgen receptor (AR), a member of the nuclear receptor superfamily. The development of global and conditional AR knockout mouse models showed that androgenic activity is required for normal follicle development and function. In the ovary, AR activation is mainly carried out by testosterone, which is produced by the theca cells of the follicle. Depending on the stage of follicle maturation, androgens exert direct autocrine and/or paracrine effects to regulate follicular function, or they can also act as a substrate for aromatase of the granulosa cells, which convert the androgens to estrogens. In females, circulating androgens including dehydroepiandrosterone, androstenedione, and dihydrotestosterone (DHT) may also participate in the regulation of ovarian function. However, only testosterone and DHT (a nonaromatizable androgen) activate the AR, while the other androgens require conversion to testosterone or DHT.

Androgen Receptor Expression in the Ovary

In the ovary, the AR is expressed in the theca-interstitial cells, in the oocytes, and in the granulosa cells. This suggests that all compartments of the follicle are putative targets of androgen action.

Theca Cells

In situ hybridization studies showed extensive AR mRNA labeling in the theca cells of rat ovaries (Hirai et al., 1994). Recently, strong AR protein labeling in the nuclei of the theca cells was also observed in mouse follicles especially after treatment with DHT. However, a decrease in AR signaling in the theca cells has no effect on steroid secretion, development, or reproductive function of females under physiological androgen levels (Ma et al., 2017).

In rhesus monkeys, the AR mRNA is detected in theca-interstitial cells of developing follicles but at distinctly lower levels than granulosa cells. Moreover, in contrast to granulosa cells, there are no significant differences between AR mRNA levels in the theca of preantral and large antral follicles. In this species, the AR mRNA is also present in the ovarian stroma (Weil et al., 1998).

The Oocyte

The AR has been detected in the oocyte of several species. Particularly in rats, the AR is clearly detectable in the oocyte of primary and secondary follicles. Interestingly, the oocyte nucleolus becomes strongly positive for the AR as the follicles grow. In mouse, expression of the AR in the oocyte is detectable by immunohistochemistry mainly in the cytoplasm, and it is virtually absent in the nucleus. The function of the AR in the oocyte in mice is still unclear as the knockout of the AR in the oocyte has no effects on female reproduction (Sen and Hammes, 2010).

Granulosa Cells

In rodents, the AR is expressed in granulosa cells of smaller follicles and steadily increases toward the early antral stage, whereas a progressive decrease has been observed from the early antral to the preovulatory stage. In rats, the abundance of AR mRNA decreases ~50% during the maturation from small to large antral follicles, whereas the abundance of aromatase mRNA increased > 250%. Immunofluorescence studies demonstrated AR protein expression in primordial, transitional, and primary follicles in mice (Laird et al., 2017). In rats, the AR protein is located predominantly in the nuclei of the granulosa layer of preantral and very early antral rat follicles. Interestingly, as follicles grow to the preovulatory stage, a decline in AR expression occurs in the mural granulosa cells closer to the basement membrane of the follicles. As follicle maturation advances, the decline in AR expression proceeds toward the antrum. However, the antral regions connected with cumulus cells and the cumulus cells themselves remain strongly positive for the AR. Thus, in preovulatory follicles, the AR is confined to the cumulus cells. High nuclear AR expression can also be observed in the expanded cumulus oophorous cells (Galas et al., 2012). These findings indicate that during the final stages of follicle maturation, the AR decline starts in the mural granulosa cells and progresses toward the antrum, but before and after ovulation, the AR remains highly expressed in the cumulus cells (Fig. 1).

In humans, the mRNA for the AR is not present in primordial follicles but appears in transitional and primary follicles. Moreover, AR immunostaining is most abundant in healthy preantral/early antral follicles and low in preovulatory follicles (Saunders et al., 2000). In premenopausal women, AR nuclear staining has been shown in granulosa cells and in a small proportion of stromal

Fig. 1 Androgen receptor (AR) expression in granulosa cells throughout folliculogenesis and primary follicular mechanisms controlled by androgens under normal conditions. Increasing intensity of red color indicates higher AR expression. *pd*, primordial; *pm*, primary; *sc*, secondary; *EA*, early antral; *PO*, preovulatory. Granulosa cells, mural and cumulus.

cells. At the protein levels, human cumulus cells express high levels of AR, but it is almost undetectable in mural cells. By ICC, it was shown that AR is present in the nucleus of cumulus cells, and it is not affected by DHT treatment. More recent findings using PCR confirmed that the AR is not detectable in primordial human follicles, but as folliculogenesis progresses, the percentage of AR positive follicles at each stage increased linearly. This report also demonstrated that early follicles acquire the AR before they express the receptor for follicle-stimulating hormone (FSHR). In rhesus monkeys, there is noticeable heterogeneity in the follicular pattern of AR gene expression, with only a subpopulation of follicles demonstrating intense AR mRNA hybridization. AR mRNA appears more abundant in small- and medium-sized follicles compared with the large preovulatory follicles. In common marmoset, there are clear differences in AR immunostaining in the granulosa cells of immature and preovulatory follicles. Thus, in this species, the average AR level in the granulosa cells of immature follicles is 4.2-fold higher than that in the granulosa cells of preovulatory follicles. These findings strongly support the importance of androgens in early folliculogenesis in higher primates including humans.

In all species studied thus far, there is an evident decline in AR expression in mural granulosa cells, which are close to the wall of the follicle. In contrast, the receptor remains highly expressed in cumulus cells, which are in close contact with the oocyte (Fig. 1). These findings suggest that androgens can play a paracrine role in oocyte maturation by controlling cumulus cells function, whereas androgens actions on mural cells wane as the follicles reach the preovulatory state. Thus, in preovulatory follicles, androgens are mainly used to produce estradiol, a role that is potentiated by the high levels of aromatase expressed by the mural granulosa cells. However, despite the progressive decline toward the preovulatory stage, the AR remains clearly detectable at the mRNA and protein levels in preovulatory mural granulosa cells of rodents and primates. The AR mRNA not only remains detectable in the granulosa cells of preovulatory follicles but also increased in response to the ovulatory gonadotropin stimulus, suggesting it may play a role during ovulation.

Genes Targeted by Androgens in the Ovary

Only a few genes have been confirmed to be direct targets of the AR in ovarian granulosa cells.

FSHR

Androgens seem to sustain FSHR expression in mouse granulosa cells, and a positive association between AR and FSHR mRNA levels has been described in small antral follicles in humans. In mice, androgens appear to increase FSHR protein levels without affecting the transcription of the *Fshr* gene (Sen et al., 2014). However, how the AR may only enhance the translation of FSHR is not understood, although paxillin, a cytoskeletal protein involved in cell adhesion to the extracellular matrix, seems to be involved. The effect of androgens on the FSHR protein synthesis does not appear to be universal as androgens were shown to increase FSHR mRNA levels by several authors. For instance, testosterone increases FSHR mRNA expression in primate primary follicles, and DHT increases FSHR in porcine preovulatory follicles. In female rhesus monkeys, testosterone also augments follicular FSHR expression.

Furthermore, global AR knockout mice showed no decrease in FSHR mRNA levels (Shiina et al., 2006), whereas other global AR knockout mice showed a decline in FSHR expression in ovaries of 10-day-old mice (Hu et al., 2004). Similarly, conditional knockout of the AR in the granulosa cells has no effect on FSHR mRNA levels when compared with controls. In addition, testosterone stimulation of mouse and rat granulosa cells does not affect FSHR mRNA or protein levels. Therefore, the role of androgen on FSHR expression is not entirely understood yet. In AR knockout females (see succeeding text), follicles develop until the antral and preovulatory stages, which are dependent on FSH actions. Therefore, even in the absence of androgen effects, FSH appears to promote follicle development suggesting that androgens are not essential for FSHR expression, at least in rodents.

Experiments using luteinized human granulosa cells showed that testosterone could increase the expression of the FSHR. However, this report used an extremely high concentration of testosterone ($> 30 \mu\text{M}$). As androgen levels in the follicular fluid are in the nanomolar range, the effects observed at these higher concentrations do not seem to have physiological importance.

IGF1 and IGF1R

In rhesus monkeys, androgen treatment results in a threefold increase in insulin-like growth factor 1 (IGF1) and a fivefold increase in IGF1R in primordial follicle oocytes (Vendola et al., 1999). Similarly, testosterone and DHT increase IGF1 mRNA levels in granulosa, thecal, and interstitial cells of small antral follicles in primates. In the same system, androgens have no effect on the expression of the insulin receptor.

Kit Ligand

Microarray analysis in ovaries of AR knockout mice identified kit ligand (kit-L) as a possible target of androgens (Shiina et al., 2006). In fact, in primary rat granulosa cells, androgens stimulate kit-L expression. In addition, androgens increase the activity of the kit-L promoter in a human granulosa cell line. Moreover, the AR binds to the kit-L promoter in living cells. These findings suggest that kit-L is a direct target of the AR in the granulosa cells.

COX2 and AREG

Exogenous gonadotropin-induced superovulation increases serum androgen levels robustly in female mice suggesting that androgens may be involved in ovulation. In fact, in rodents, DHT treatment induces the expression of prostaglandin-endoperoxidase synthase 2 (COX2) and of epidermal growth factor-like factor, amphiregulin (AREG), which both are involved in ovulation. These genes are also induced by DHT in granulosa tumor-derived cells. Further studies demonstrated the presence of androgen-response sequence(s) upstream of COX2 and AREG, and that these regions are occupied by the AR in periovulatory granulosa cells.

Cyclin D2

In rat granulosa cells, DHT inhibits FSH-mediated granulosa cell proliferation by reducing cyclin D2 mRNA expression causing cell cycle arrest at the G1/S interphase. DHT exerts this inhibitory effect on cyclin D2 mRNA expression by reducing FSH-mediated phosphorylation of ERK via inhibition of protein kinase A. In these cells, DHT also reduces insulin-mediated cyclin D2 mRNA expression (Kayampilly and Menon, 2006).

miR-125b

In mouse granulosa cells, the AR targets miR-125b. The authors demonstrated the presence of AR response elements in the miR-125b promoter and revealed that the AR binds to the miR-125b promoter only in the presence of androgens.

Role of Androgens in Folliculogenesis

Currently, it is widely accepted that androgen actions change from stimulation to inhibition as follicles mature. Moreover, it has been suggested that inappropriately high levels of androgens promote follicular atresia. Here, we will briefly describe known effects of androgens throughout folliculogenesis.

Primordial Follicles

Androgens promote the initiation of primordial follicle growth in mice, sheep, and primates. However, it has been shown that primordial human follicles do not express the AR. Therefore, it is expected that this effect of androgen is indirect via androgen activation of primary and secondary follicles, which in turn produce factors, such as IGF1, that stimulate primordial follicle activation.

Preantral and Early Antral Follicle

In primates, bovines, and rodents, androgens promote early follicle growth. In vitro findings demonstrated that testosterone and DHT improve the survival of preantral follicles in primates. In rhesus monkeys, DHT rescues follicle growth after treatment with drugs that inhibit steroid synthesis. In rhesus monkeys, high levels of AR mRNA correlate with elevated levels of granulosa cell proliferation and the absence of apoptotic cell death in these same follicles. In contrast, low or undetectable levels of AR mRNA are associated with barely detectable proliferation but abundant apoptotic cell death (Weil et al., 1998). Testosterone stimulates the primary to secondary follicle transition in fetal bovine ovaries, an effect that is inhibited by antagonists of the AR. Also in bovines, testosterone promotes the growth of follicles, whereas estradiol has no effects, suggesting that the effect of testosterone

is not due to its conversion to estradiol. Recent findings in rats demonstrated that DHT promotes follicle growth in a stage-dependent manner via changes in granulosa cell proliferation and apoptosis. Thus, androgen stimulation of preantral follicles increases rat granulosa cell proliferation and decreases apoptosis. The combination of these effects augments follicular growth. However, androgens effects on follicle growth and antrum formation seem to follow a biphasic pattern. Thus, low levels of androgens induce follicle maturation, while high levels inhibit oocyte maturation and follicle growth (Lebbe et al., 2017).

Large Antral to Preovulatory Follicles

At the antral stage, androgens may have positive or adverse effects on follicular growth (Fig. 2). In rat granulosa cells of antral follicles, androgens augment the stimulatory effect of FSH on estradiol, aromatase, and plasminogen expression. On the other hand, androgens increase follicular atresia and inhibit FSH-induced granulosa cell proliferation in antral follicles. Moreover, in primates, it has been shown that DHT inhibits the production of estradiol, which is exclusively produced by antral follicles. Strikingly, AR antagonists can amplify the stimulatory effects of FSH and LH, suggesting that endogenous androgens block gonadotropin-stimulated ovulation. In fact, in primates, high concentrations of DHT are antagonistic to gonadotropin-stimulated ovarian function. The mechanisms involved in these differential effects of androgens during folliculogenesis remain to be determined.

Finally, in rhesus monkeys, AR expression increases during the induction of ovulation along with a temporary rise in androstenedione levels in the follicular fluid. This suggests that androgens may also play a role in the periovulatory follicles. In mice lacking the AR, treatment with gonadotropins causes an increase in apoptosis in antral follicles (see succeeding text). These results suggest that the AR plays a significant role in granulosa cell survival during the periovulatory stage, and the absence of AR may cause granulosa cells to be more susceptible to apoptosis.

Effect of the AR Knockdown on Female Fertility

Female global AR knockout mice are distinctively subfertile (Shiina et al., 2006; Hu et al., 2004). All global AR knockout female mice produce fewer pups/litter and exhibit abnormal estrous cycles, which in the mutant animals are longer and irregular. Interestingly, the ovaries of AR knockout mice contain a typical population of follicles at least up to 16 weeks of age. However, older AR knockout females exhibit an accelerated depletion of the follicle pool with a complete loss of follicles by 40 weeks of age. Atresia is also significantly increased in the ovaries of AR knockout mice. In general, evidence from the AR knockout mice suggests that the observed reduction in the numbers of pups produced by AR knockout females is due to dysfunctional follicular growth and the development of fewer preovulatory follicles (Fig. 2).

Mice that express a mutant AR lacking the DNA binding domain show a similar phenotype to the global knockouts, which include subfertility, dysfunctional follicle development, ovulation disruption, and age-dependent subfertility (Walters et al., 2007). Therefore, classical genomic AR-mediated effects are critical for optimal follicle growth and successful ovulation.

The knockdown of the AR specifically in the granulosa cells also leads to impaired fertility, with reduced numbers of litters and smaller litter sizes and irregular cyclicity (Sen and Hammes, 2010). However, the knockdown of the AR in the theca cells or in the oocyte has no major effects on female reproduction (Ma et al., 2017; Sen and Hammes, 2010). This suggests that the role of androgens in female fertility is mainly mediated by their regulation of granulosa cell function.

The deletion of the AR in the pituitary does not alter the estrous cycles, but these animals are also subfertile and produce fewer pups per litter (Wu et al., 2014). In these animals, all follicle populations are normal except for a decrease in antral follicles and

Fig. 2 A decrease or an excess of androgens significantly alter the normal progress of folliculogenesis. See Fig. 1 for more details.

corpora lutea count. Pituitary-specific AR knockout females also have reduced FSH levels at proestrus and diminished ovulatory LH levels. This suggests that AR signaling in the pituitary plays a significant role in maintaining optimal gonadotropin levels.

In humans, androgen depletion also reduces fertility. Indeed, patients with diminished ovarian reserve appear to have an androgen deficiency and benefit from androgen supplementation. However, this clinical practice remains controversial because the most basic ovarian mechanisms controlled by androgens remain unknown. This controversy is also fueled by the fact that elevated androgen levels are associated with poor reproductive health. For instance, hyperandrogenemia is present in up to 70% of women with PCOS, a disease that significantly reduces fertility and has an incidence of 6%–10% in reproductive-aged women. Thus, the evidence available clearly indicates a delicate equilibrium between beneficial and harmful effects of androgens in female reproduction.

Conclusions

The evidence supports an important role of androgens in follicle growth and ovarian function. Androgens appear to participate in follicle development from the initiation of primordial follicle growth all the way to ovulation. During this process, the granulosa cells are the primary target of the androgens, although a neuroendocrine effect of androgens may also participate in the regulation of normal ovarian function. Most strikingly, it is clear that optimal androgen levels are required for normal ovarian function. Thus, diminished androgenic activity leads to subfertility, while androgen excess negatively affects ovulation. The mechanisms that control the balance between harmful and beneficial effects of androgens in ovarian function are starting to be elucidated.

Glossary

Dehydroepiandrosterone (DHEA) 19-Carbon androgen synthesized in the adrenal glands, gonads, and brain; it can also have a sulfate group attached (DHEA-S).

DNA methylation Process by which a methyl group is attached to DNA; increases or decreases in this process determines if a DNA sequence can be transcribed into RNA.

Endogenous A protein or hormone that is normally synthesized by a cell or tissue in the body.

Endoplasmic reticulum A structure in the cytoplasm of a cell; it usually has ribosomes attached and is involved in protein and lipid synthesis by a cell.

Epiphyseal fusion The epiphysis is located at the end of long bones and is the site of bone growth; at the end of adolescence the epiphysis fuses with the rest of the bone effectively terminating future bone growth.

Exogenous A factor (organic or synthetic) that is produced outside of the body.

Exon Segment of RNA sequence that contains the coding information for a protein or peptide.

Formic acid A simple carboxylic acid with the chemical formula HCOOH; an intermediate in chemical synthesis reactions.

Genitalia Organs associated with reproduction; commonly used to describe the external reproductive organs.

Genome Complete set of genes or genetic material present in a cell.

Gonad Organ that produces germ cells or gametes; in mammals, it refers to the ovary which produces oocytes or testis which produces sperm.

Histone modifications Histones are proteins that DNA wraps around within the nucleus of a cell; each histone protein has a tail which can have acetyl, phosphate, or methyl groups attached; these modifications to histone tails regulate DNA transcription rates.

Homozygous Having identical pairs of genes (one on each chromosome pair) for any given hereditary characteristic.

Kinases Enzyme that catalyzes the transfer of a phosphate group from ATP to a specific protein or molecule; important regulator of signal transduction.

Missense mutation A change in a single nucleotide of DNA; when copied to mRNA the mutation causes a switch in the amino acid added to the protein.

Nicotinamide adenine dinucleotide phosphate (NADPH) Cofactor used in anabolic chemical reactions associated with the synthesis of lipids and nucleic acids.

Osteopenia Condition of lower than normal bone mineral density; precursor to osteoporosis.

P450 oxidoreductase An enzyme inserted in the endoplasmic reticulum membrane which transfers electrons from NADPH to other cytochrome P450 enzymes (e.g., aromatase).

Phenyl ring Cyclic group of atoms with the formula C₆H₅.

Senescence Biological aging; in the context of the ovary it refers to depletion of oocytes in the ovary and marks the end of reproductive function in the female.

Sexually dimorphic nucleus (SDN) of the preoptic area (POA) Cluster of cells within the brain; located in the anterior hypothalamus and thought to be an important determinant of sexual behavior.

Transcription Biological process of synthesizing an RNA message (mRNA); copy of the DNA gene sequence.

Translation Biological process of synthesizing protein from mRNA; mRNA code is recognized and determines how amino acids are added to the growing protein.

Virilization Development of male physical characteristics in a female or a boy prior to puberty; usually occurs due to exposure to excess androgens.

X-ray crystallography A technique that uses X-ray technology to examine the structure of DNA or a protein which is captured in a crystal.

Introduction

Estrogens are a class of 18-carbon steroid hormones that, like all steroid hormones, are synthesized from cholesterol. In mammalian species, a series of enzymatic reactions result in conversion of cholesterol into one of three endogenously produced estrogens; estrone, estradiol, and estriol (**Fig. 1A**). The common characteristic of all three estrogens is the presence of a phenyl ring (**Fig. 1A**) which is the result of a final aromatization step. The substrates for this irreversible aromatization reaction are androgens,

Fig. 1 (A) Chemical structure of estrone, estradiol, and estriol. (B) Schematic showing androgen substrates that are converted to specific estrogens by the enzyme aromatase. Based on DiNardo, G. and Gianfranco, G. (2013). Human aromatase: perspectives in biochemistry and biotechnology. *International Union of Biochemistry and Molecular Biology* **60**, 92–101.

a class of 19-carbon steroids. Specifically, the immediate steroid precursor for estrone is androstenedione while testosterone is the precursor to estradiol and 16 α -hydroxytestosterone is the precursor to estriol (Fig. 1B). The focus of this article is on the enzyme aromatase, which catalyzes the aromatization of each 19-carbon androgen into an 18-carbon estrogen. The regulation of aromatase expression and activity, which represents an important regulatory aspect of the physiological actions of estrogens, will also be discussed.

Conversion of Androgens to Estrogens Is Regulated by the P450 Enzyme, Aromatase

Aromatase is a single enzyme that belongs to the cytochrome P450 family. This family includes enzymes involved in drug metabolism and hormone biosynthesis and degradation. Like many of its family members aromatase is located in the endoplasmic reticulum of the cell. Purification and sequencing of the aromatase protein was accomplished in the 1980s using tissues from several species including human placenta. These studies showed that the aromatase protein sequence is highly conserved between mammalian species especially in the predicted androgen binding site. Recently, the three-dimensional structure of the protein was also defined. Using X-ray crystallography, investigators identified not only how the protein is folded into its final structure but also the site where androstenedione binds (Ghosh et al., 2010). In addition to the binding site for androstenedione, and presumably other androgens, a binding site for NADPH and cytochrome P450 oxidoreductase (CPR) which are essential for the activity of aromatase, was also identified. Interestingly, CPR is a common partner of all cytochromes P450 and therefore is expressed throughout the body.

The consensus is that the aromatase enzyme catalyzes three independent steps that convert androgens to estrogens (Yoshimoto and Guengerich, 2014; Di Nardo and Gilardi, 2013). The first two steps are well established hydroxylation reactions (Fig. 2). During the third step, the 19th carbon is released as formic acid due to a demethylation reaction which concomitantly causes the formation of the characteristic phenolic ring of estrogen (Fig. 2). However, the exact sequence of biochemical events associated with this third step is still under investigation. The energetic cost of this three-step enzymatic reaction is the consumption of oxygen (Fig. 2). Likewise, the reactions require the donation of electrons from NADPH to aromatase which is mediated by CPR. The product of the reaction is of course estrone, estradiol, or estriol dependent on the substrate used in the reaction (e.g., Fig. 2 shows conversion of androstenedione to estrone).

Aromatase Is Expressed in a Variety of Tissues

Ovary and Placenta

The aromatase protein is normally expressed in a wide variety of cells and tissues in both males and females (Table 1). The classic and most abundant site of estrogen synthesis is the female ovary. Specifically, aromatase is expressed in granulosa cells and to a lesser extent theca cells (Corbin et al., 2003), which are the somatic cells within the ovary that directly surround oocytes. Aromatase is also expressed in the ovarian corpus luteum (Tripathy et al., 2016), a transient ovarian cell type that arises from theca and granulosa cells after oocyte ovulation. Due to the high levels of aromatase activity in the ovary, the primary estrogen produced in pre-menopausal women is estradiol, which is secreted into the circulation and therefore acts as an endocrine hormone. As described above, the substrate for this aromatase is testosterone which in humans is predominately produced by the theca cells. The placenta, a transient organ essential for pregnancy, is also a significant source of aromatase activity in women. Indeed, as indicated above, the placenta was an important tissue source for aromatase protein purification. Within the placenta, aromatase synthesizes all three estrogens;

Fig. 2 Chemical reaction whereby androstenedione is converted to estrone. The consumption of oxygen (O_2) and use of NADPH at each step (1–3) are indicated. The production of formic acid in the third and final step of the reaction is indicated as well. Based on Yoshimoto, F. K. and Guengerich, F. P. (2014). Mechanism of the third oxidative step in the conversion of androgens to oestrogen by cytochrome P450 19A1 steroid aromatase. *Journal of the American Chemical Society* **136**, 15016–15025.

Vascular endothelium

that is, estrone, estradiol, and estriol. The result of placental aromatase is a 100-fold increase in circulating estrone and estradiol in women at the end of pregnancy. Furthermore, there is a 1000-fold increase in circulating estriol in pregnant compared to non-pregnant women. Interestingly, as pregnancy progresses, the predominate source of androgen substrates is the fetus (Kaludjerovic and Ward, 2012). Specifically, within the fetal adrenal gland, dehydroepiandrosterone sulfate (DHEA-S) is produced from maternal cholesterol. The DHEA-S is subsequently converted to androstenedione, testosterone, or 16 hydroxytestosterone by placental enzymes which are then converted to estrone, estradiol, or estriol by aromatase.

Testis

In the last few decades, the importance of aromatase expression and activity in the male testis has become fully realized. In adult animals and humans, the primary site of aromatase expression is in the Leydig cells which are a steroidogenically active somatic cell of the testis. Because the major androgen synthesized by Leydig cells is testosterone, the major estrogen produced by testicular aromatase is estradiol. Like the ovary, testis-derived estradiol enters the circulation; however, the concentration is significantly less than the amount of estradiol secreted by the ovary. Interestingly, studies in numerous species also show aromatase expression in developing and mature sperm (Haverfield et al., 2011). It is hypothesized that aromatase produces local estrogens which may regulate sperm motility; although, additional studies are required to confirm this finding. Finally, aromatase expression has been detected in the epididymis which is an important site of sperm storage. The estradiol produced within the epididymis is important for regulating the environment within this compartment where the final steps in sperm maturation occur that result in its ability to effectively fertilize eggs (Haverfield et al., 2011).

Brain

In addition to the gonads, distinct regions of the brain express aromatase which results in localized synthesis and action but not significant secretion of estrogens. Within the hypothalamus, conversion of testosterone to estradiol by aromatase is important

for endocrine regulation of gonad function particularly in males. Likewise, aromatase activity is positively correlated to the expression of male sexual behaviors. These reproductive effects are best described in the male brain due to increased availability of circulating substrate (i.e., testosterone) and increased responsiveness of aromatase within the male brain to the circulating androgens (Roselli et al., 2009). Aromatization of testosterone to estradiol in the fetal brain is also an important determinant of sexual behavior in the adult male. Based on studies in sheep, rats, mice and pigs, it appears that differential development of the sexually dimorphic nucleus (SDN) of the preoptic area (POA) of the brain, which is an important site that determines sexual behavior including partner preference, is correlated to aromatase activity. Specifically, in male fetuses, testosterone from the fetal testis is converted to estradiol in neural tissue of the POA which results in development of the SDN. Furthermore, the production of estradiol increases the expression and activity of the neural aromatase. Alternatively, in female fetuses, there is low circulating testosterone and therefore local estrogen synthesis and SDN development is significantly reduced. Interestingly, the female brain can be masculinized if the fetal brain is exposed to exogenous testosterone. Likewise, the male brain can be feminized if aromatase expression or activity is impaired in the developing POA. While these hypothalamic sites are important for reproductive function and behaviors, local aromatase activity within the hippocampus, cerebral cortex, and spinal cord produces estrogen which contributes to neural health particularly at sites of neural injury. Interestingly, it appears that aromatase is also expressed by neurons including at the site of neuron-to-neuron communication and therefore may influence important functions including cognition, memory, and sensory perception (e.g., pain) (Roselli, 2007).

Adipose Tissue and Bone

Aromatase is also expressed in several other extragonadal tissues in men and women (Stocco, 2012). For example, its expression and activity in bone cells is correlated with increased bone density. Likewise, adipose tissue is a significant source of aromatase activity. Interestingly, expression and activity of aromatase in adipose tissue increases with age making it an important source of estrogens, particularly in post-menopausal women. It should be noted that like aromatase activity in the brain, the majority of estrogen synthesized by aromatase within these non-reproductive tissues are not released into the circulation but rather stay and act locally in the surrounding tissue. Reviews on additional functions of locally-produced estrogens in extragonadal tissues can be found in Simpson et al. (2000).

Regulation of Aromatase Expression Is Tissue Specific

Expression of the aromatase protein is positively correlated with transcriptional activity at the gene encoding its messenger RNA (mRNA). The aromatase gene is called *CYP19* and it spans approximately 130 kilobases on human chromosome 15. Human *CYP19*, a single copy gene, is arranged into 10 exons with exons II-X containing the coding sequence for the aromatase protein. Exon I encodes for untranslated sequence of the mRNA and together with the DNA proximal to exon I (i.e., the promoter) contributes to the regulation of *CYP19* mRNA synthesis. Ten alternative exon I sequences have been identified in human tissues that express *CYP19* (Fig. 3). For example, exon I.1 is transcribed in placenta whereas exon I.6 is transcribed in bone. Alternatively, in both male and female gonads, transcription starts in exon IIa which is located adjacent to the common exon II (Fig. 3). Interestingly, the

Fig. 3 Schematic organization of the *CYP19* gene which is located on human chromosome 15. The translational start site (ATG) and alternative exon I sequences are indicated. Tissue specific expression of alternative exon I sequence is also indicated in the table. Based on Bulun, S. E., Sebastian, S., Takayama, K., Suzuki, T., Sasano, H. and Shozu, M. (2003). The human *CYP19* (aromatase P450) gene: update on physiologic roles and genomic organization of promoters. *Journal of Steroid Biochemistry and Molecular Biology* **86**, 219–224.

promoter and alternative exon I used in a particular cell type is often altered if/when it transforms into a cancer cell. For example, adipocytes associated with breast cancer cells express *CYP19* mRNA from exon IIa rather than exon I.4 which is used in normal adipocytes (Fig. 3). In contrast to the human genome, the genomes of some other species contain more than one *CYP19* gene. For example, in pigs, there are three different *CYP19* genes which produce three similar but unique aromatase proteins in gonads, placenta, and embryo (Kamat et al., 2002). Likewise, goldfish and zebrafish genomes contain two copies of the *CYP19* gene one of which is expressed in the gonads and the other in the brain.

The genomic arrangement (i.e., the use of alternative exon I and promoter sequences) of human *CYP19* provides regulatory diversity of its expression in the absence of gene duplication. Indeed, an important area of research is understanding tissue-specific regulation of *CYP19* transcription by different growth factors and signaling pathways. These collective studies have, to date, been performed using predominately in vitro cell culture models. Future studies will be required to fully understand the complexities by which transcription and signaling factors regulate the expression of *CYP19* within diverse cells and tissues. In addition to these traditional mechanisms of transcriptional regulation, interesting novel regulators of *CYP19* mRNA abundance have been identified. For example, in the turtle fetus, temperature changes alter DNA methylation and histone modifications resulting in increased or decreased aromatase expression within the developing gonad (Matsumoto et al., 2016). In this way, temperature determines development of the female ovary versus the male testis in developing turtles. Recent studies also show an important role for micro RNAs in the regulation of *CYP19* mRNA abundance. MicroRNAs (miRs) are small non-coding pieces of single stranded RNA that bind to messenger RNAs and promote their degradation and/or inhibit mRNA translation. In developing placental cells, miR-17~92 and miR-106a~363 bind to and reduce the amount of *CYP19* transcripts (Kumar et al., 2013).

Despite the differential expression of the unique exon I (or IIa) sequences in unique tissue and cell types, each first exon joins with the common exon II at the same nucleotide position. Furthermore, the translation of aromatase protein initiates within the common exon II; and therefore, the same aromatase protein is produced in each cell and tissue. It is important to note growing evidence that regulation of aromatase enzyme activity is also an important regulatory mechanism particularly in cells where local estrogen production is rapidly increased or decreased. An example of this type of regulation has been described in quail brain and cell lines expressing human aromatase. Specifically, these studies show that the rate of aromatase enzymatic activity is rapidly decreased when the protein has a phosphate group added to specific amino acids by calcium-dependent and calcium-independent kinases (Charlier et al., 2011).

Aromatase Deficiency Causes Abnormalities in Reproductive and Non-Reproductive Systems

Genetic mutations in the human aromatase gene are rare. In fact, prior to the 1990s it was believed that the loss of aromatase expression would result in embryonic or fetal loss. However, missense mutations in the *CYP19* gene have since been identified in a small number of individuals (Bulun, 2014). Homozygous mutations in *CYP19* render the aromatase enzyme essentially inactive resulting in dramatic reductions in circulating estrogen. In females, the loss of aromatase is immediately apparent. Due to the loss of placental derived estrogens, the female fetus exhibits masculinized external genitalia. Furthermore, disrupted communication between the ovary and pituitary results in pubertal failure and multi-cystic ovaries. In the male, the loss of aromatase activity associated with genetic mutation in the *CYP19* gene is not apparent until after puberty. In the adult male, sperm are immotile resulting in infertility. There is also reduced male libido although the severity of this phenotype is variable. Interestingly, women who are pregnant with a fetus carrying a *CYP19* mutation also exhibit phenotypes associated with virilization including increased acne and hirsutism. These phenotypes are a result of reduced placental estrogen production combined with increased fetal adrenal androgen synthesis; however, it is a transient condition which resolves after parturition.

In addition to reproductive phenotypes, both males and females with a *CYP19* mutation have abnormalities in bone growth. Specifically, there is increased linear growth due to a lack of epiphyseal fusion and at the same time osteopenia resulting in reduced bone density. Individuals carrying a *CYP19* mutation are also at increased risk for metabolic dysfunction due to insulin resistance and abnormal lipid metabolism. Interestingly, post-menopausal women, who experience a natural drop in aromatase expression due to ovarian senescence, experience similar bone and metabolic phenotypes. Clinically, these phenotypes can be reversed by estrogen replacement. It should be noted that an aromatase knock-out (ArKO) mouse model was generated in 1998 by two independent groups (Simpson et al., 2005). Phenotypes of the ArKO mouse include reproductive abnormalities, bone density loss, insulin resistance, obesity, and lipid excess in the liver and are consistent with the phenotypes identified in humans with a naturally occurring *CYP19* mutation.

Aromatase Inhibitors Represent Important Therapeutics Against Estrogen Excess

While estrogen deficiencies associated with *CYP19* mutations are rare, estrogen excess associated with benign (endometriosis, stunted growth) and malignant (cancers of the breast, uterus, and prostate) disease is quite prevalent in the human population. Estrogen excess is generally due to increases in local rather than circulating estrogen production. For example, altered exon I and promoter usage leads to increased estrogen production by adipose tissue within the mammary gland (Fig. 3). In some cases, aromatase is abnormally expressed in a tissue. Indeed, it is the abnormal expression and activity of aromatase in uterine stroma which increases local estrogen levels and results in development of endometriosis. Alternatively, increases in estrogen may be simply due

Fig. 4 Chemical structure of aromatase inhibitors including a steroidal analog (exemestane) and non-steroidal molecules (letrozole, anastrozole). Based on Dunkel, L. (2006). Use of aromatase inhibitors to increase final height. *Molecular and Cellular Endocrinology* **254–255**, 207–216.

to increases in the amount of adipose tissue which some individuals carry (i.e., obesity). To combat estrogen excess, aromatase inhibitors have been designed which bind to the enzyme and prevent the binding of endogenous C19-androgens. Unlike androgens, these synthetic molecules cannot be aromatized and this causes dramatic decreases in the amount of locally produced estrogen. Inhibitors that are currently used clinically include exemestane, anastrozole, and letrozole (Fig. 4, note their structural similarity to androgens). Given the potential ability of aromatase inhibitors to combat breast cancer and endometriosis, new inhibitors that are more potent, more stable, and have greater specificity (i.e., they do not inhibit any other P450 enzymes) are desired. Therefore, this is an active area of current research (Ghosh et al., 2016).

Glossary

Autocrine When a cell secretes a chemical messenger that acts back on that same cell.

Affinity The strength of the interaction between a receptor and its ligand.

β -strand A polypeptide chain of 3–10 amino acids with backbone in an extended conformation.

Competitive receptor antagonist An agent that displaces an endogenous ligand by binding to the same site on the receptor, without activating downstream intracellular signaling.

Corpus luteum The remnant of the ovarian follicle following ovulation; and the principal source of progesterone during the luteal phase.

Cystine-knot Protein structure composed of three disulfide bridges (between pairs of cysteine residues). Two of the bridges form a loop through which the third bridge passes.

Dimeric A protein that is composed of two subunits (can be different or identical).

Estrus The stage of the female rodent reproductive cycle during which the female is sexually receptive following ovulation.

Follicle The functional unit of the ovary, which is composed on the oocyte surrounded by somatic cells.

Furin A protein belonging to the proprotein convertase family. A calcium-dependent serine protease that cleaves precursor proteins.

Gonadotrope cell/gonadotropes A cell type of the anterior pituitary gland that produces the gonadotropins: LH and FSH.

Gonadotropins Dimeric glycoprotein hormones produced by gonadotrope cells. LH and FSH are the canonical members of this protein hormone family; however, human chorionic gonadotropin (hCG) and equine chorionic gonadotropin (eCG), secreted from the placenta, are also considered gonadotropins.

Granulosa cell Somatic cells within the ovarian follicle that surround the oocyte. They produce estrogens and inhibins.

Kinase Enzymes that catalyze phosphorylation reactions.

Luteal cell The cells that comprise the corpus luteum. They produce progesterone and, in humans, inhibin A.

Paracrine When a cell secretes a chemical messenger that acts on neighboring cells.

Proestrus The stage of the female rodent reproductive cycle just prior to ovulation. High levels of estrogens trigger the LH surge on the afternoon of proestrus.

Prohormone A precursor form of a hormone that must be processed (usually by proteolysis) into the biologically active form.

Proteoglycan Proteins with glycosaminoglycan chains covalently attached.

Radioimmunoassay A test used to quantitatively measure concentrations of hormones in circulation or in tissues.

Theca cell Somatic cells of the ovarian follicle that produce androgens in response to LH. Theca cells are the outermost layer of the follicle, encapsulating the granulosa cells.

Introduction

Reproduction is a complex physiological process controlled by hormones from the brain (hypothalamus), pituitary gland, and gonads (ovaries, in the case of females) (Fig. 1). The classical hormones in this hypothalamic-pituitary-gonadal (HPG) axis are gonadotropin-releasing hormone (GnRH) from the brain, the pituitary gonadotropins (FSH and LH), and the gonadal steroid hormones (e.g., estrogens and progesterone). GnRH is released from the brain into the pituitary portal vasculature and stimulates the synthesis and secretion of both follicle-stimulating hormone (FSH) and luteinizing hormone (LH) by gonadotrope cells in the anterior pituitary. FSH and LH then travel via the bloodstream to the ovary, where they stimulate follicle growth (Fig. 2), estrogen production, and ovulation. Through a process called negative feedback, estrogens travel back to the brain to slow the rate of GnRH release and, consequently, FSH and LH secretion. A lesser known, but equally important, hormonal feedback system exists between the gonads and the pituitary in which protein hormones called inhibins (Fig. 3) travel from the ovary (and testes) to suppress FSH, but not LH, synthesis directly at the pituitary level. Inhibins suppress FSH by blocking the actions of activins, which are produced in the pituitary and promote FSH synthesis. Inhibins and activins also play local roles in the ovary, regulating follicle development. In this article, we describe the history of inhibin and activin research, the structure of the proteins, and how they regulate both pituitary and ovarian function.

Fig. 1 Schematic representation of the hypothalamic-pituitary-gonadal axis. The hypothalamus secretes pulses of GnRH that enter the pituitary portal vessels at the level of the median eminence and thereby reach gonadotrope cells of the anterior pituitary gland. There, GnRH stimulates the production and release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH and FSH enter the general circulation to reach the ovary where LH stimulates the production of androgens by theca cells; FSH stimulates granulosa cell proliferation and estrogen production. LH also stimulates ovulation. The remnants of the ovulated follicles form corpora lutea, which produce progesterone. Progesterone and estrogens enter the general circulation and feedback on the hypothalamus and the pituitary gland to negatively regulate the release of GnRH, and LH and FSH, respectively. Estrogens can also have positive feedback effects, promoting GnRH and LH release prior to ovulation. Gonadotropes also secrete activins, which act in an autocrine/paracrine fashion to specifically stimulate FSH. Activin signaling, and therefore FSH synthesis and secretion, is antagonized by inhibins from the ovaries. -ve, negative feedback. +ve, positive feedback. Green and red arrows/lines denote positive and negative arms of the axis. Estrogen feedback can be both negative and positive (in females) and is depicted with yellow arrows.

Discovery of Inhibins and Activins

Inhibin was discovered, or at least hypothesized, in the late 1920s to early 1930s. Scientists observed that removing the testes from rats (i.e., castration) caused structural changes (specifically hypertrophy) in a subset of cells of the anterior pituitary gland. These “castration” cells, as they were then called, are now known to be gonadotropes, which produce FSH and LH. As these large cells emerged only following castration, researchers reasoned that the testes must produce factors that regulate pituitary cell function,

Fig. 2 Stages of ovarian follicle development. Follicles are formed in embryonic (human) or early postnatal (rodent) development. Primordial and primary follicles contain an oocyte surrounded by a single layer of immature or mature granulosa cells (blue). As follicles begin to grow to the secondary stage, granulosa cells proliferate, the oocyte grows, and the follicle becomes encapsulated by theca cells (black line encircling follicles). These early stages of follicle development occur in the absence of gonadotropins. Once follicles reach the early antral stage, their growth into preovulatory (antral/Graafian) follicles is driven by FSH. Following the mid-cycle surge of LH, the large follicle(s) ovulate (not pictured). The remnants of the follicle then transdifferentiate into the corpus luteum, which secretes progesterone and, in the case of primates, inhibin A. The fluid filled antra are labeled. Inhibins and activins were purified from this follicular fluid.

Fig. 3 Schematic representation of activins and inhibins. Top: The three inhibin subunits (inhibin α , β_A , and β_B) are composed of a pro-domain and a C-terminal mature region. The prodomain of inhibin α is cleaved in two; the large product is referred to as αN . The mature domain of inhibin α is referred to as αC . Middle: The different subunits can hetero- or homodimerize to form precursor forms of the inhibin and activin molecules. The mature regions are linked by intermolecular disulfide bonds (*thick vertical lines*). The prodomains are essential for dimerization and protein folding. The *arrows* indicate where furin and related proteases cleave the precursor molecules. Bottom: The mature forms of the inhibin (A or B) and activin (A, B, or AB) ligands.

either directly or indirectly. In an effort to determine the nature of these factors, investigators fractionated fat- and water-soluble components of the testes and injected them back into castrated rats. The water-soluble fraction prevented the formation of castration cells. As testosterone (then called androinitin) is fat-soluble, these results indicated that it was not a steroid hormone that regulated castration cells. Instead, researchers proposed that there must be a new hormone linking the testes and the pituitary. They dubbed this hormone “inhibin.”

Attempts to purify inhibin from testicular tissue were uniformly unsuccessful from the 1930s–1960s. With the benefit of hindsight, we now know that much of this failure derived from the fact that the adult testis produces relatively low amounts of inhibins, making it a poor source for protein purification. Research in the 1970s, however, represented a rebirth of inhibin research. Development of radioimmunoassays for FSH and LH in the mid-1960s enabled quantitative analyses of both hormones from the blood and tissues. Using these assays, researchers discovered that testicular extracts and ovarian follicular fluid (from the antrum of large follicles; Fig. 2) contained water-soluble proteins that could selectively suppress FSH secretion without affecting LH in castrated mice. They reasoned that these proteins were likely the long-sought inhibin and realized that its activity was that of a selective FSH inhibitor. As a result, the hypertrophy of gonadotrope (castration) cells reflected the increase in FSH synthesis in the absence of inhibin negative feedback.

Armed with the information that follicular fluid (which could be acquired in large volumes from cows, pigs, and sheep in slaughterhouses) was a rich source of inhibin, researchers now only needed an assay (test) in which to purify the protein(s). They found such a system in the form of cultured rat pituitary glands. When placed in culture, pituitary cells continue to produce FSH and LH, and secrete the hormones into the culture medium where they can be measured. When pituitary cultures were treated with unfractioated follicular fluid, they showed selective decreases in FSH secretion. These results demonstrated that inhibin could affect the

pituitary directly, and not indirectly via the hypothalamus and GnRH. With this powerful in vitro culture assay in hand, researchers biochemically processed large volumes of follicular fluid and honed in on the components (fractions) that retained selective FSH-suppressing activity. This purification procedure led to the isolation of two forms of inhibin (inhibin A and inhibin B) as well as a structurally-unrelated protein (follistatin), which selectively suppressed FSH (i.e., did not affect LH secretion). Serendipitously, and unexpectedly, two other proteins with structural similarity to the inhibins were purified, but were found to selectively stimulate FSH secretion. These proteins were dubbed activins (in this case, activin A and activin AB; Fig. 3). It was subsequently shown that follistatins bind and bionutralize the activins. Follistatins are the subject of another chapter in this volume and are therefore not considered in detail here.

Structure of Inhibins and Activins

The purification of inhibins from follicular fluid lead quickly to their molecular characterization as dimeric proteins of an α subunit (inhibin α) disulfide-linked to one of two β subunits (inhibin β A and inhibin β B; Fig. 3). The three proteins are derived from different genes on chromosomes 2 (α and β B) and 7 (β A), and are expressed as preprohormones. The amino-terminal prodomains are essential for proper folding and dimerization of the biologically active carboxy-terminal mature domains. Prodomains are cleaved from the mature domains by furin or related enzymes. Dimers of mature inhibin α with inhibin β A form inhibin A, whereas the inhibin α -inhibin β B heterodimer constitutes inhibin B. Remarkably, despite their opposing actions, activins are formed through homodimeric or heterodimeric bonding of inhibin β subunits. In the context of reproduction, three activins have been described: Activin A (β A- β A), B (β B- β B), and AB (β A- β B) (Fig. 3). Despite their high sequence identity, the β subunits (and hence the activin and inhibin isoforms) have both common and distinct biological functions, the latter of which are dictated by differences in their patterns of expression and their structures.

Inhibins and activins are members of the transforming growth factor β (TGF β) superfamily of secreted ligands, which includes TGF β s, growth differentiation factors, bone morphogenetic proteins, anti-Müllerian hormone, and nodal. Like other proteins in the family, inhibins and activins are secreted from cells noncovalently linked to their prodomains. Prodomain association can restrict the actions of other TGF β family members, but not the inhibins and activins. Indeed, recent data suggest that the inhibin α prodomain may actually facilitate receptor binding of the mature hormone, though the underlying mechanism is presently unresolved. Nonetheless, the mature dimer must eventually dissociate from the prodomains to bind to cell surface receptors or other binding proteins. Both inhibins and activins can be detected in the bloodstream, but only inhibins appear to act as bona fide hormones. Inhibins have short half-lives in circulation (less than 10 min). As a result, changes in circulating inhibins (e.g., Fig. 7) are directly linked to changes in subunit expression in the ovary. That is, when inhibin subunits are down-regulated, circulating levels of the hormone quickly decrease. Most activins in the bloodstream are bound to follistatins, which appear to irreversibly block activin action. Follistatins bind activins in a 2:1 stoichiometry (two molecules of follistatin for every activin dimer), blocking receptor binding sites on the ligand. Rather than functioning as hormones, activins instead act in autocrine or paracrine fashion, like most members of the TGF β family.

Inhibins and activins adopt a growth factor-like fold, classically described as a hand with a pair of reciprocating anti-parallel β -strands (representing four fingers), a central helix (representing the wrist) and an amino-terminal segment representing the thumb (Fig. 4A). A cystine-knot motif is found within the fingers near the wrist helix where two disulfide bonds from finger 2 to finger 4 form a ring-like structure. The knot-like structure comes from a third disulfide bond that loops through the center of the ring, joining fingers 1 and 3. Near the cystine-knot is an additional unpaired cysteine that forms the intermolecular disulfide bond linking the two monomers (Fig. 4B). This brings the two monomers together at the central wrist helix with the fingers from each monomer extending in different directions, giving the dimer a propeller or butterfly appearance (Fig. 4B, top).

Activin and Inhibin Signaling Mechanisms

In general, TGF β family members signal in cells through a conserved mechanism in which the dimeric proteins bind to complexes of transmembrane serine/threonine kinase receptors. Though there are 33 genes encoding TGF β ligands (subunits), there are only 12 receptors for the whole family. Thus, ligands share receptors. These receptors fall into two general classes: type I and type II. There are seven type I and five type II receptors in mammals. Both receptor types have extracellular amino-terminal domains, a single transmembrane domain, and an intracellular carboxy-terminus that contains the kinase domain. In general, the dimeric ligand binds to heterotetrameric complexes of two type II and two type I receptors (e.g., Figs. 4C and 5). Different ligands associate with receptors in different ways. In the case of activins, the ligand binds first to the type II receptors. The lower affinity type I receptors are then recruited into the complex. Other family members bind first to the type I receptor, others may bind to preassembled receptor complexes, and others require co-receptors (accessory membrane proteins) to engage type I or II receptors.

Regardless of the order of ligand binding, upon complex formation, type II receptors phosphorylate the associated type I receptors in a juxtamembrane domain referred to as the GS box. This activates the type I receptor kinases, enabling them to phosphorylate their intracellular substrates, the best known of which are the SMAD proteins. SMAD is a contraction of SMA and MAD (mothers against decapentaplegic), the founding members of the family in *Caenorhabditis elegans* (worms) and *Drosophila melanogaster* (flies), respectively. There are eight SMADs in mammals, which come in three forms: receptor-regulated (R-SMAD), common (SMAD4),

Fig. 4 Structure of activins and inhibins. Structural representation of the (A) activin A (individual βA subunit) monomer and (B) two views of the activin A dimer. In panel A, the four fingers are numbered. (C) The relative location of receptor binding sites for activin A. Note how the knuckles of the fingers of each monomer contact distinct type II receptors (green), which are positioned at opposite ends of the dimeric ligand. The structure of activin A bound to its type I receptor has not yet been solved. The positioning of the type I receptors here (blue) is modeled based on structures of other ligands and receptors in the family. Note how each type I receptor is predicted to bind at the dimer interface. (D) The structure of inhibin alone or in complex with receptors has not been solved. Here, we show a homology model of inhibin A and the predicted positioning of the activin type II receptor. The Xs denote how the presence of the α subunit (in blue) prevents binding of a second type II receptor and both type I receptors.

Fig. 5 Mechanisms of activin and inhibin regulation of FSH synthesis. Activins bind to complexes of type I (blue rectangles) and type II (green rectangles) receptor serine-threonine kinases. The type II receptors phosphorylate (P in red circles) the type I receptors in their juxtamembrane GS-domains. The type I receptors then phosphorylate SMAD3 on C-terminal serine residues. Phosphorylated SMAD3 then forms complexes with SMAD4, which accumulate in the cell nucleus. SMAD3/4 complexes partner with the transcription factor forkhead box L2 (FOXL2) and bind to the proximal promoter of the follicle-stimulating hormone β subunit gene (*Fshb*). SBE, SMAD binding element. FBE, FOXL2 binding element. Inhibins bind to complexes of the activin type II receptor and the TGF β type III receptor, betaglycan. Type I receptors are not recruited into these complexes. As a result, inhibins do not signal in cells and prevent activins from doing so.

and inhibitory (SMADs 6 and 7) (**Fig. 6**). R-SMADs and SMAD4 have a common domain structure with an amino-terminal MAD homology domain (MH1) and carboxy-terminal MH2 domain, joined by a variable linker region. The R-SMADs (SMADs 1, 2, 3, 5, and 8) are phosphorylated by type I receptors on serine residues at their extreme carboxy-termini. Phosphorylated R-SMADs then dissociate from the receptors and form heteromeric complexes, via their MH2 domains, with themselves and/or the common SMAD (SMAD4). These SMAD complexes then translocate to and accumulate in the nucleus. The MH1 domains of R-SMADs (except full-length SMAD2) and SMAD4 have a DNA binding domain, enabling them to interact directly with target genes to regulate transcription. SMAD3 and SMAD4 can bind a simple DNA sequence, GTCT (or its reverse-complement, AGAC). However, this binding is relatively weak; therefore, SMADs usually partner, again via their MH2 domains, with other DNA-binding proteins for higher affinity and specificity interactions.

Activins can bind to at least three type II receptors: the two activin type II receptors (ACVR2A and ACVR2B) and the bone morphogenetic protein receptor type II (BMPRII). They can similarly bind to at least three type I receptors (also known as activin receptor-like kinases or ALKs): ACVR1A (ALK2), ACVR1B (ALK4), and ACVR1C (ALK7); however, activin binding to wild-type ALK2 does not activate intracellular (SMAD) signaling. Interestingly, activin B and activin AB, but not activin A, can signal via ALK7. ALK4 is the primary signaling receptor for activin A. This demonstrates functional consequences for the structural (sequence) differences between the β subunits. ALK4 and ALK7 preferentially phosphorylate SMAD2 and SMAD3. As such, these SMADs are classically considered the principal signaling molecules activated downstream of activin receptor complexes. Phosphorylated SMAD2 and SMAD3 form complexes with SMAD4 before accumulating in the nucleus. The stoichiometry of these complexes is not entirely clear and may be context-specific. According to X-ray crystallographic studies, the MH2 domains can form trimers of two R-SMADs and one SMAD4.

Mechanisms of inhibin action are not fully described, particularly in vivo, but extant data converge to suggest that inhibins function as endogenous competitive receptor antagonists. By virtue of sharing β subunits with activins, inhibins can bind to activin type II receptors, which occurs exclusively through the β subunit (**Fig. 4D**). However, inhibins do not functionally bind type I receptors and therefore cannot propagate intracellular signals via classical TGF β pathways (i.e., via SMAD proteins). This is due to the α -subunit, which is expected to disrupt the type I binding surfaces that are formed at the interface of the two chains (**Fig. 4D**). Since inhibins only have one type II binding epitope they bind the type II receptors with 10-fold lower affinity than activins and are therefore weak antagonists on their own. However, in the presence of the TGF β type III receptor (TGFR3, also known as betaglycan), inhibins can form high affinity complexes with type II receptors that potently block activin binding and signaling (**Fig. 5**). Inhibins bind betaglycan via their α subunits, explaining why activins do not share this co-receptor. Betaglycan is a transmembrane proteoglycan. Inhibins bind the juxtamembrane portion of the extracellular domain. The intracellular carboxy-terminus of betaglycan lacks known functional motifs and is therefore not considered a signaling receptor. Instead, it acts to facilitate binding of inhibins (and TGF β isoforms) to type II receptors.

Fig. 6 Schematic representation of SMAD protein domain structures. SMAD proteins can be classified into three categories: (top) receptor-regulated (R-SMADs); (middle) common (co-SMAD); and (bottom) inhibitory (I-SMADs). Both R-SMADs and SMAD4 possess an N-terminal MAD homology 1 domain (MH1), which confers DNA binding activity via a β -hairpin structure that inserts into the major groove of DNA. Full-length SMAD2 cannot bind DNA because an additional exon (exon 3) introduces a sequence near the β -hairpin that sterically hinders DNA binding. The MH1 domain also encodes the nuclear localization signal (NLS), which directs the protein to the nuclear compartment. This activity is counteracted by the nuclear export signal (NES) in the MH1 (SMAD4) or C-terminal MH2 domain (R-SMADs). The linker domain can be phosphorylated by various kinases (such as ERK, AKT, JNK, and PI3K) and can regulate transactivation and binding to different partners. The SMAD activation domain (SAD) in the SMAD4 linker region is required for transcriptional activity. The MH2 domain, present in all SMADs, is essential for protein-protein interactions. The R-SMADs are phosphorylated by the type I receptors in their SSXS motif at the extreme C-terminus of the MH2 domain.

Inhibin and Activin Regulation of Follicle-Stimulating Hormone Synthesis

The main source of circulating inhibins is the ovary (and testes in males). Indeed, ovariectomy reduces inhibins in the blood to undetectable levels. Inhibin A and B are dynamically regulated across female reproductive cycles and are produced by different cell types, in species-specific fashion. In humans, inhibin B is principally produced by granulosa cells of growing follicles during the follicular phase of the menstrual cycle, whereas inhibin A is mainly derived from the corpus luteum following ovulation (Fig. 7A). In rats, inhibin B is produced by granulosa cells of small follicles, whereas inhibin A is the product of large, preovulatory follicles. As such inhibin B is elevated through most of the estrous cycle, where inhibin A increases steadily to a peak on the afternoon of proestrus (Fig. 7B). The preovulatory surges of LH (and FSH) down-regulate inhibin α production, leading to a rapid decline in circulating inhibins. In response to this loss of negative feedback, the pituitary gland rapidly upregulates FSH synthesis and secretion, leading to a 'secondary surge' of FSH on the morning of estrus, which drives the next wave of follicle development (Fig. 7B). Indeed, inhibins and FSH are strongly negatively correlated throughout the rat estrous cycle. Whether inhibins similarly restrain FSH during the human menstrual cycle is a matter of some debate; however, it is clear that inhibin B is the major negative feedback modulator of FSH in male primates. Also, perimenopausal increases in circulating FSH correlate more with loss of inhibin B than estrogen negative feedback. There is ample evidence to support the notion that inhibin B contributes to the pattern of FSH release during the follicular phase of the menstrual cycle. Whether inhibin A restrains FSH secretion during the luteal phase is less clear.

As indicated above, inhibins function as receptor antagonists. They therefore suppress FSH by blocking the actions of other proteins, most likely the activins, rather than by generating intracellular signals of their own. According to current dogma, pituitary gonadotrope cells produce activin B (the homodimer of $\beta\beta$ subunits). Activin B then acts on the gonadotrope cell that made it (autocrine) or on neighboring gonadotropes (paracrine) to stimulate FSH synthesis. The mechanisms through which activins regulate FSH synthesis have been most thoroughly characterized in mice. Some, though perhaps not all, of the mechanisms are likely to be conserved across mammalian species, including humans. FSH is a dimeric protein composed of the glycoprotein α subunit (not to be confused with the inhibin α subunit) noncovalently bound to the FSH β subunit. FSH β is rate-limiting in the production of FSH and activins stimulate transcription of the FSH β gene (*Fshb*). In the current model, activin B binds to complexes of ACVR2A and ALK4 or ALK7. The latter then phosphorylate SMAD3, which partners with SMAD4 and translocates into the nucleus. SMAD3/4 complexes then partner with the forkhead transcription factor FOXL2 and bind to the promoter (regulatory sequence) of the *Fshb* gene (Fig. 5). Some aspects of this model await in vivo validation. In particular, it is unclear whether ACVR2A is the only

Fig. 7 Schematic representation of inhibin and FSH secretion across the human menstrual (top) and rodent estrous cycles (bottom). The figures show relative, not absolute amounts of inhibin A (blue), inhibin B (green), and FSH (red) in circulation. The different stages of the cycles are labeled. The approximate timing of ovulation (gray box) is shown. Ovulation is triggered by a surge of LH (not pictured, but the timing coincides with that of the primary FSH surge just before ovulation).

type II required or which type I receptors play a role. Genetic studies in mice also indicate that activin B is unlikely to be the only TGF β family member that stimulates the *Fshb* gene. Finally, there is some suggestion that activins not only stimulate *Fshb* transcription but also increase the half-life of the *Fshb* mRNA. This latter mechanism has not been investigated in detail.

Roles for Inhibins and Activins in the Ovary

Although best known for their roles in the selective regulation of FSH synthesis and secretion, inhibins and activins were first purified from follicular fluid and, indeed, have important local actions in the ovary. In fact, many intra-ovarian TGF β family members play essential roles in follicle development. Ovarian follicles consist of germ cells (oocytes) surrounded by somatic cells (granulosa and theca) (Fig. 2). The number and nature of these cells depends on the stage of follicle development. Immature (primordial or primary) follicles are surrounded by a single layer of granulosa or pregranulosa cells. As follicles mature, the granulosa cells proliferate and, themselves, become surrounded by theca cells. TGF β ligands are made by and act in oocytes, granulosa, and theca cells. Inhibin and activin subunits, however, are principally expressed in granulosa cells and, in some species, in luteal cells.

Our understanding of the intra-ovarian actions of inhibins and activins is incomplete; however, both appear to regulate steroid hormone production and granulosa cell proliferation, at least in certain contexts. Androgens (like androstenedione and testosterone) are produced by theca cells in response to pituitary LH. Inhibins stimulate and activins inhibit thecal androgen biosynthesis. As with FSH synthesis, activins appear to be the main actors in the system, with inhibins antagonizing their actions. Granulosa cells produce estrogens, principally in response to FSH. Here, FSH stimulates production of the aromatase enzyme, which converts theca-derived androgens into estrogens. Activin actions in granulosa cells are complex, and are both age- and developmental-stage dependent. For example, in follicles from immature mice, activins can potentiate the effects of FSH on granulosa cell proliferation and estrogen biosynthesis, in part by upregulating FSH receptor levels. However, in older mice, activins actually block FSH-stimulated follicle growth. It is presently unclear how activins produce these opposing activities.

Genetic studies in mice demonstrate important roles for inhibins and activins in follicle development and ovarian tissue homeostasis *in vivo*. Mice lacking the inhibin α subunit (*Inha* $-/-$) develop sex-cord stromal tumors beginning around 4 weeks of age. This observation led to the concept that inhibins act as tumor suppressors in the gonads and that excess activin signaling may promote tumor development. In the absence of the inhibin α subunit, the ovaries fail to make inhibins and instead produce excess activins, as β subunits can freely homo- or hetero-dimerize. These activins appear to contribute to tumor formation, as mice lacking both inhibin α and the activin type IIA receptor (*Acr2a*) show slower tumor progression than mice lacking inhibin α alone. However, *Acr2a* $-/-$ mice also have reduced FSH levels (because of impaired activin signaling in the pituitary). Therefore, it is possible that the loss of both activin and FSH action in the ovaries explains the slowing of tumor growth in these mice. Consistent with this idea, deletion of the *Fshb* gene (and therefore FSH) similarly slows tumor growth in *Inha* $-/-$ mice. Tumor development is entirely blocked in *Inha* $-/-$ mice lacking both FSH and LH. These data indicate a fundamental role for gonadotropins in gonadal tumor formation in *Inha* $-/-$ mice. More recent data also indicate that the loss of inhibin or gain of activin action may alter how the gonads respond to gonadotropins. Prior to tumor development, juvenile *Inha* $-/-$ mice exhibit aberrant ovarian physiology, with precocious granulosa cell development. When treated with exogenous gonadotropins these animals fail to produce antral follicles. Thus, both gonadotropin-independent and -dependent aspects of ovarian follicle development are dysregulated in the absence of inhibin (and/or in the presence of enhanced activin) action in the ovary.

Mice lacking inhibin β subunits display distinct phenotypes to those of *Inha* $-/-$ mice. Inhibin β A subunit knockout mice (*Inhba* $-/-$), which cannot make activin A, activin AB, or inhibin A, die shortly after birth. Inhibin β B subunit knockout (*Inhbb* $-/-$) develop relatively normally and are fertile; though the females exhibit impaired maternal behavior. These data suggest that activin B, activin AB, and inhibin B do not play essential roles in female fertility in mice or that activin A and inhibin A can compensate in their absence. Deletion of the inhibin β A subunit specifically in granulosa cells leads to subfertility, whereas mice lacking both β subunits in the ovary are sterile. These mice have complex, but intriguing ovarian phenotypes. There are no apparent alterations in the numbers of primordial, primary, or secondary follicles, suggesting that activins (and inhibins) may not be required for follicle formation or early (gonadotropin-independent) stages of follicle development. However, these animals, especially those lacking both β subunits, have increased numbers of antral (gonadotropin-dependent) follicles and an unusually large number of corpora lutea. Enhanced antral follicle development likely derives from elevated FSH levels (again due to loss of inhibin negative feedback). The increased numbers of corpora lutea may indicate a role for activins in regression of corpora lutea (luteolysis). That is, corpora lutea may persist in the absence of activin signaling.

Summary and Conclusions

Inhibins were first postulated in the 1930s, but were only purified over 50 years later. The following year, the activins were unexpectedly discovered as the yang to the yin of inhibins. Over the past 30 years, we have learned a great deal about how inhibins and activins are synthesized and how they act in cells. In the last 15 years, we have come to understand how activins (or related proteins) regulate FSH synthesis, the context in which they were discovered and, in fact, named. Though inhibins appear to act as receptor antagonists, this has not yet been confirmed *in vivo*. Biochemical analyses have revealed the three-dimensional structure of activins, how they bind to their type II receptors, and how they are antagonized by follistatins. Comparable structures for inhibins are needed

but are currently lacking. Though inhibins and activins were discovered in the context of reproduction, it is now abundantly clear that they play diverse roles during development and adulthood, in health and disease. For example, inhibins have been proposed to regulate bone physiology, whereas activins regulate muscle mass and stem cell fate. As we approach the 100 year anniversary of the naming of inhibin, it is exciting to ponder what the next century of inhibin and activin research will reveal.

TGF β Family

The human transforming growth factor β (TGF β) superfamily, which includes > 35 members, is the largest family of growth factors in vertebrates. TGF β signaling regulates development and adult tissue homeostasis through context-dependent and cell-type-specific actions. The superfamily is named for the first member discovered, TGF β 1, which was first detected as one of two fractions, the first dubbed TGF α and the second TGF β , purified from acid-ethanol extracts of murine sarcoma cells transformed by Moloney sarcoma virus that enabled large colonies of normal rat kidney epithelial cells to grow in soft agar. Purification of the TGF β 1 peptide from human tissues confirmed that this transforming factor had a role in normal biology. Although first identified for its ability to promote anchorage-independent growth in vitro, it soon became clear that TGF β has cell-type- and context-dependent effects. Subsequent studies demonstrated that TGF β 1 is one member of a family of structurally-related ligands.

The TGF β family operates through a shared mechanism. The signaling cascade is initiated by a ligand homodimer or heterodimer binding to and bringing together pairs of type 1 receptor kinases with pairs of type 2 receptor kinases. This newly formed transmembrane receptor complex allows the type 2 receptor kinase to phosphorylate the type 1 receptor kinase, removing a conformational block on the kinase domain of the type 1 receptor and activating it. The activated type 1 receptor kinase can then phosphorylate receptor SMADs, allowing the receptor SMADs to form heterotrimeric complexes of two phosphorylated receptor SMADs and one common SMAD (co-SMAD, SMAD4). This receptor SMAD/SMAD4 complex concentrates in the nucleus, where it regulates gene expression directly and through interactions with numerous cofactors. This process is outlined in Fig. 1.

There are three major groups of related ligands within the TGF β family: the bone morphogenetic protein (BMP)/growth differentiation factor (GDF) group, the activin/nodal group, and the TGF β group. These groups all have partially overlapping preferences for type 1 receptor kinases, dubbed activin receptor-like kinases (ALK), each of which acts through one of two distinct sets of receptor SMADs. The BMP/GDF group binds ALK1, 2, 3, and 6, which phosphorylate SMAD1, SMAD5, and SMAD8. The activin/nodal group binds ALK4 and 7, which phosphorylate SMAD2 and SMAD3. The TGF β group binds ALK1, 2, 3, and 5; however,

Fig. 1 The basic mechanism of TGF β family signaling. (A) Binding of the ligand dimer to two type 1 receptor kinases and two type 2 receptor kinases. (B) Upon ligand binding, the type 2 receptor kinase phosphorylates the type 1 receptor kinase, activating it. (C) The activated type 1 receptor kinase phosphorylates the receptor SMADs, which, once phosphorylated, form a heterotrimeric complex with SMAD4, which remains unphosphorylated. (D) The SMAD complex concentrates in the nucleus, where it regulates gene expression as a transcription factor by binding DNA with the cooperation of a wide array of cofactors.

Table 1 Type 1 receptor kinase interactions

Type 1 receptor	Alternate symbol	Ligands	R-SMAD
ALK1	ACVRL1	BMPs, TGF β s	SMAD1/5/8
ALK2	ACVR1A	BMPs, GDF5/6/7/9b/10/11/15, AMH, TGF β s	SMAD1/5/8
ALK3	BMPR1A	BMPs, GDF5/6/7/9b/10/11/15, AMH, TGF β s	SMAD1/5/8
ALK4	ACVR1B	myostatin, GDF1/3/9, activins, nodal	SMAD2/3
ALK5	TGFR1	myostatin, GDF1/3/9, TGF β s	SMAD2/3
ALK6	BMPR1B	BMPs, GDF5/6/7/9b/10/11/15, AMH	SMAD1/5/8
ALK7	ACVR1C	myostatin, GDF1/3/9, activins, nodal	SMAD2/3

R-SMAD is an abbreviation for receptor SMAD.

TGF β typically signals through ALK5, which phosphorylates SMAD2 and SMAD3. Type 1 receptor kinase interactions with ligands and receptor SMADs are detailed in [Table 1](#).

The type 2 receptor kinase binding follows a different pattern: activin receptor type 2A (ACVR2A) and activin receptor type 2B (ACVR2B) can bind BMPs, GDFs, and activin/nodal; BMP receptor type 2 (BMPR2) can bind BMPs; TGF β receptor type 2 (TGFR2) exclusively binds the TGF β s; and anti-Müllerian hormone receptor type 2 (AMHR2) exclusively binds AMH, a BMP-group ligand. Type 2 receptor kinase interactions with ligands are detailed in [Table 2](#).

Because of its critical roles in development and adult tissue homeostasis, the TGF β family includes regulators that can promote or inhibit signaling. Regulation occurs primarily at two levels, the TGF β family ligands by factors that sequester and bind ligands and the receptor SMADs by factors that regulate receptor SMAD phosphorylation.

Ligand binding to the type 1 and 2 receptor kinases is regulated by secreted ligand-binding proteins and by membrane-anchored co-receptors. Secreted ligand-binding proteins bind TGF β family ligands, preventing them from interacting with the type 1 and 2 receptor kinases. Follistatin, chordin, noggin, cerberus, gremlin, DAN, and follistatin-like proteins 1 and 3 are examples of ligand-binding proteins that regulate signaling through preferential binding to specific sets of ligands ([Table 3](#)). Similarly, membrane-anchored co-receptors bind TGF β family ligands to regulate ligand signaling; however, the effects of co-receptors on ligand signaling are more variable than those of secreted ligand-binding proteins. Co-receptor binding can promote ligand signaling, as in the case of betaglycan, which is required for TGF β 2 binding to TGFR2 or cripto, which facilitates nodal interactions with ALK4/7. Co-receptor binding can also inhibit signaling, as in the inhibition of activin signaling by cripto, which complexes with activin but prevents activin from binding its type 2 receptors. Additional examples of co-receptor regulation include DRAGON, a BMP co-receptor; repulsive guidance molecule (RGM), a BMP co-receptor; and endoglin, a co-receptor that interacts with ALK1 and 5 to regulate TGF β and BMP signaling ([Table 4](#)).

Receptor SMADs are regulated before and after phosphorylation. Receptor SMAD phosphorylation is promoted by recruitment of receptor SMADs to type 1 receptor kinases by anchor proteins; SMAD anchor for receptor activation (known as SARA) recruits SMAD2/3 and endoglin recruits SMAD1/5/8. Phosphorylation of receptor SMADs is also negatively regulated. The inhibitory

Table 2 Type 2 receptor kinase interactions

Type 2 receptor	Ligands
BMPR2	BMPs, GDFs
ACVR2A	BMPs, GDFs, myostatin, activins, nodal
ACVR2B	BMPs, GDFs, myostatin, activins, nodal
TGFR2	TGF β s
AMHR2	AMH

Table 3 Secreted ligand binding proteins

Secreted proteins	Target ligands
Follistatin	Activin; myostatin; BMP2, 4, 5, 6, 7, 15; GDF11; TGF β 3
Chordin	BMP2, 4, 7
Noggin	BMP2, 4, 5, 6, 7; GDF5, 6
Cerberus	BMP2, 4; nodal
Gremlin	BMP2, 4, 7
DAN	BMP2, 4; GDF5
Follistatin-like protein 1	BMP4
Follistatin-like protein 3	Activin; myostatin; BMP2

Table 4 Membrane-anchored co-receptors

Coreceptors	Targets	Action
betaglycan	TGF β 2	Promotes ligand binding to TGFBR2
cripto	nodal, activin	Promotes nodal binding to ALK4/7 Inhibits activin binding to type 2 receptors
DRAGON	BMP2, 4	Promotes binding to type 1 and type 2 receptors
RGM	BMP2, 4	Promotes binding to type 1 and type 2 receptors
endoglin	ALK1, ALK5	Promotes signaling through ALK1 and ALK5

Table 5 SMAD proteins

Name	Type	Summary
SMAD1	receptor SMAD	Phosphorylated by ALK1/2/3/6
SMAD2	receptor SMAD	Phosphorylated by ALK4/5/7
SMAD3	receptor SMAD	Phosphorylated by ALK4/5/7
SMAD4	common SMAD	Binds phosphorylated receptor SMADs
SMAD5	receptor SMAD	Phosphorylated by ALK1/2/3/6
SMAD6	inhibitor SMAD	Inhibits receptor SMADs
SMAD7	inhibitor SMAD	Inhibits receptor SMADs
SMAD8	receptor SMAD	Phosphorylated by ALK1/2/3/6

SMADs, SMAD6 and SMAD7, compete with receptor SMADs for access to activated type 1 receptor kinase. SMAD6 also continues to regulate receptor SMADs after phosphorylation, binding them and preventing complex formation with SMAD4. Mammalian SMAD family members are described in [Table 5](#).

In addition to signaling through phosphorylation of receptor SMADs, activated TGF β family type 1 receptors can phosphorylate non-SMAD cytoplasmic proteins to regulate ERK MAPK, JNK/p38 MAPK, Rho-like GTPase, and PI3K/AKT signaling pathways. Termed non-canonical TGF β signaling, these alternative signaling pathways play important roles in cancer and may have underappreciated roles in normal biology. The effects of non-canonical TGF β signaling include promoting epithelial to mesenchymal transition, migration, and invasion—cell behaviors critical in cancer, embryonic development, and placentation.

Follistatin

Discovery of Follistatin

The discovery of follistatin is intimately connected to the discovery of its signaling partners inhibin and activin. The concept of an inhibiting factor was originally articulated by Dr. Douglas Roy McCullagh in 1932 who proposed that a water-soluble hormone capable of abrogating gonadotrophin secretion by the pituitary is produced by the testis. The term inhibin was subsequently refined to refer to the factor produced by the gonads that regulates the secretion of follicle-stimulating hormone (FSH) by the pituitary and numerous studies were conducted to attempt to isolate the responsible protein. The development of a reliable and specific bioassay for regulation of basal FSH production, the rat anterior pituitary monolayer culture system, allowed protein extracts to be tested for inhibin activity. In 1985, three groups purified two highly similar 32 kDa proteins that inhibited FSH production in the bioassay from porcine ovarian follicular fluid. Their inhibins, termed inhibin A and B, were composed of a 20 kDa amino-acid chain and a 14 kDa amino-acid chain bound together by disulfide bonds. Subsequent studies would reveal that inhibin A and B are actually heterodimers formed of inhibin α with one of two inhibin β subunits, A or B, and that homo- and heterodimers formed by two inhibin β subunits have an opposite effect on pituitary FSH secretion, leading inhibin β dimers to be termed activins. Follistatin entered this mix as an incidental finding reported in the original papers describing the discovery of inhibin. A side fraction of the protein purification that isolated inhibin also had the ability to inhibit FSH secretion in the bioassay, but it was less potent, leading the original studies to focus on inhibin. Purification of the FSH secretion-inhibiting protein from the side fraction revealed a 35 kDa protein termed follistatin.

Biological Activity of Follistatin

The mechanism behind the FSH secretion inhibition by follistatin was uncovered when characterization of an activin-binding protein in the rat ovary showed the activin-binding protein was follistatin. Although initially described as a regulator of the pituitary, it quickly became clear that activin has diverse biological roles and belongs to a family of structurally-related secreted factors, the transforming growth factor β (TGF β) family. Follistatin binds not only activin, but other TGF β family ligands, including

Fig. 2 The structure of follistatin and the generation of its three protein isoforms. FST288 and FST315 are generated through alternative splicing in exon 6 and FST305 is generated through proteolytic cleavage of FST315.

myostatin, BMP2, 4, 6, 7, 15, GDF11, and TGF β 3. However, follistatin strongly prefers binding to activin rather than to BMPs. Follistatin inhibits ligand activity by preventing binding of the ligand to its receptor complex. Follistatin also promotes clearance of its ligands through uptake of cell surface heparin-bound follistatin-ligand complexes, which are subsequently targeted for lysosomal degradation.

Structure of Follistatin

Characterization of the porcine and human cDNAs revealed the primary structure of follistatin. Follistatin has six exons expressed as two isoforms, FST288 and FST315, with alternate splicing of exon six in the smaller FST288 isoform. As a secreted protein, follistatin is expressed as a precursor of 317 or 344 amino acids with a 29-amino acid signal peptide that is proteolytically cleaved to generate a final product of 288 or 315 amino acids (Fig. 2). The FST288 and FST315 isoforms differ in their localization; FST288 is found tethered to cell surface-bound heparins, allowing it to act locally on paracrine and autocrine activin signaling whereas FST315 is the primary isoform in serum and can inhibit endocrine activin signaling. A third isoform, FST303, is produced by proteolytic cleavage of FST315 and shows similar localization to FST288 (Fig. 2). Structural studies show that follistatin is composed of an N-terminal unique domain, three consecutive repeated follistatin-like domains (Fs1, 2, 3), and, in the FST315 isoform, a C-terminal acidic tail. Each follistatin-like domain of 70–74 amino acids is composed of two subdomains—an epidermal growth factor (EGF)-like subdomain of ~30 amino acids and a Kazal protein inhibitor-like subdomain of ~40 amino acids. The three Fs domains bind target ligands, with Fs1 and Fs2 required for ligand binding, and Fs1 contains the heparin-binding domain. The C-terminal acidic tail of the FST315 isoform can interact with the heparin-binding domain, modulating its affinity for heparin from negligible to strong, based on local salt concentrations and whether FST315 is bound to a target ligand. The crystal structures of follistatin bound to two target ligands, activin A and myostatin, have been described. One follistatin molecule binds each monomer of the activin or myostatin dimer. In the case of activin, the convex surface of activin, which interacts with the type 2 receptor binding site, is blocked by the Fs1 and Fs2 domains of follistatin; however, the concave surface of activin, which interacts with the type 1 receptor binding site of myostatin, is not occluded. In contrast, both the type 2 and type 1 receptor binding sites of myostatin are blocked by follistatin, with the type 1 receptor binding site bound by the N-terminal domain of follistatin. Although crystal structures of the interaction between follistatin and BMPs have not been reported, sequence similarity/identity between BMPs and activin suggests a similar mode of binding that does not cover the type 1 receptor binding site of BMPs.

Mouse Models of Follistatin Dysfunction

Multiple transgenic models have been produced to study follistatin function (see Table 6).

Follistatin Knockout

Follistatin knockout mice are born at expected Mendelian ratios, but have multiple developmental defects and die within hours of birth because they fail to breathe. Development of muscles, bone, and skin are disrupted. Muscle mass is reduced, particularly in the diaphragm and intercostal muscles, likely leading to the respiratory failure. Skeletal defects include absent or delayed incisor

Table 6 Reproductive phenotypes of follistatin mouse models

Manipulation	Reproductive phenotype
knockout	Perinatal lethal; none reported
overexpression	Infertile; thin uteri, block in folliculogenesis, FSH deficient
hFST315 on <i>Fst</i> KO	Infertile; postnatal uterine developmental defects, uterine inflammation, premature ovarian failure
hFST288 on <i>Fst</i> KO	Perinatal lethal; none reported
FST315 KO	Subfertile; premature ovarian failure
<i>Fst</i> cKO by <i>Amhr2-cre</i>	Subfertile; premature ovarian failure
<i>Fst</i> cKO by <i>Pgr-cre</i>	Subfertile; embryo attachment failure and defective decidualization

cKO, conditional knockout.

development, cleft or soft palates, abnormalities in the thirteenth pair of ribs, and missing lumbar vertebrae. Skin is shiny and taut. Whiskers are unusually thin and improperly oriented. No defects in the development of the female reproductive tract were reported. Because follistatin null pups die shortly after birth, the effects on reproduction cannot be studied using a constitutive knockout.

Follistatin Overexpression

To study the roles of follistatin in reproduction and development, a gain-of-function mutant mouse model with overexpression of follistatin was developed. Adult females have reproductive defects, including small thin uteri, variable ovarian defects ranging from an early block in folliculogenesis before antral follicle formation to a block in the early primary follicle stage, and reduced concentrations of FSH. This model cannot distinguish between the effects of lower FSH concentrations on reproduction and possible roles of follistatin in the ovary and uterus.

Single-Isoform Follistatin Knockout

Because follistatin knockout is perinatal lethal, several studies have sought to use knockouts of only one of the two follistatin isoforms to study both general and isoform-specific roles of follistatin.

To study the isoform-specific roles of follistatin, mice that expressed FST315 or FST288 isoforms with native human promoter sequences on a *Fst* KO background were generated. hFST288 expressing mice are similar to *Fst* KO mice, exhibiting similar phenotypes and surviving only slightly longer. hFST315-expressing mice survive past birth and grow to adulthood, allowing the effects of FST288 knockout to be assessed. Females are infertile with ovarian and uterine abnormalities. Folliculogenesis is disrupted with fewer follicles of all stages, including no antral follicles or corpus luteum observed at 7 weeks of age. The phenotype appears to worsen over time with young adult mice displaying estrous behavior, but losing the behavior as they age, suggesting that hFST315 mice suffer from premature ovarian failure. Uterine development is abnormal, with dramatically shorter uterine horns and vagina. Uteri of hFST315 females respond abnormally to mating, with leukocyte infiltration in the lumen and disruption of the luminal epithelium that is consistent with an inflammatory response. Three key limitations of the study make interpreting the reproductive phenotypes difficult. First, expression of hFST315 is under the control of human, not mouse, promoters. Expression of hFST315 is reduced relative to wild-type FST315, making this a FST-deficient model in addition to a FST315-only model. It is also possible that hFST315 expression does not follow the expression pattern of wild-type FST315. Second, it is difficult to distinguish between the effects of FST288 absence during development and in the adult, particularly on uterine and ovarian function. Third, the severe ovarian defects make any analysis of the uterine phenotype difficult. The absence of corpus luteum indicates that the uteri would have been exposed to estrogen, but not progesterone. This could account for the inflammation phenotype independent of follistatin insufficiency. It could also account for uterine developmental abnormalities as later stages of uterine development are ovarian dependent. To attempt to address these limitations, the reproductive phenotypes of this mouse model were further characterized. The follow-up study showed that the abnormal reproductive tract observed in hFST315-only females arises from defects in postnatal uterine development, not embryonic Müllerian duct development. It also examined whether removing the ovaries would improve the inflammatory phenotype seen in adult uteri, but found that whereas estrogen treatment of ovariectomized hFST315 mice does increase leukocyte abundance in the uterus, removing the ovaries does not eliminate the abnormally high baseline number of leukocytes. These data are difficult to interpret given the developmental and hormonal abnormalities of hFST315-only mice prior to ovariectomy.

In an alternative approach, mice expressing only the FST288 isoform were generated by deleting the splice acceptor site within intron 5. Unlike mice with hFST288 expression on a FST KO background, which could not rescue perinatal lethality, FST288-only mice survive to adulthood allowing reproductive phenotypes to be studied. FST288-only females are subfertile with 25% smaller litters and fewer litters per month. In FST288-only females, the primordial follicle pool is significantly larger; however, this pool is depleted to wild-type amounts by 40 days of age and decreases to below wild-type levels by 100 days of age. The higher initial number of primordial follicles is matched by greater numbers of primary and secondary, but not antral follicles, suggesting that

there is a defect in folliculogenesis. Supporting this, FST288-only mice have a significantly reduced response to superovulation. No uterine phenotypes were reported.

***Amhr2-cre* cKO of Follistatin in the Ovary**

To study the roles of follistatin in the ovary, mice with a conditional knockout (cKO) of follistatin in the granulosa cells of the postnatal ovary were generated. This was achieved using an allele of follistatin with LoxP sites flanking exons 2 through 6 and *Amhr2-cre*, which expresses Cre in the granulosa cells of all secondary and small antral follicles and in the myometrium of the uterus, but not in primordial and primary follicles nor in the uterine endometrium. *Amhr2-cre Fst* cKO mice are subfertile, producing less than half as many pups per litter and litters per month. An ovarian phenotype is not apparent at 3 months of age when follicles of all stages are present in *Amhr2-cre Fst* cKO mice. However, at 6 months of age, fewer antral follicles and corpora lutea are observed. At 8 months of age, the phenotype is even more pronounced with few follicles of any stage present. In line with the ovarian defects observed, *Amhr2-cre Fst* cKO mice have elevated levels of FSH and LH. *Amhr2-cre Fst* cKO mice also have reduced testosterone levels starting at 6 months of age, a symptom of premature ovarian failure in women. Altogether, the data suggest follistatin regulates folliculogenesis and supports oocyte survival.

***Pgr-cre* cKO of Follistatin in the Uterus**

The roles of follistatin in the uterus have been addressed in a recent study, which describes a cKO of follistatin in the uterus using Progesterone Receptor Cre (*Pgr-cre*). *Pgr-cre* acts on the epithelium and stroma of the uterus, allowing roles in the uterus to be studied. *Pgr-cre Fst* cKO mice are infertile or severely subfertile, producing only 2% of the pups generated by control mice over a 4-month breeding trial. Uteri of *Pgr-cre Fst* cKO mice fail to become receptive to embryo attachment despite normal ovarian function. The failure of uterine receptivity in *Pgr-cre Fst* cKO mice is characterized by luminal epithelial proliferation and aberrant expression of mucin-1 and e-cadherin at 3.5dpc when the epithelium must stop proliferating and differentiate to become receptive to embryo attachment. In the absence of follistatin, activin signaling is increased while BMP signaling, critical for uterine receptivity, is decreased in the uterus. The expression of E2-regulated genes is also increased, possibly because of cooperation between activin and E2 signals. Although the roles of follistatin during mid- or late-gestation periods cannot be assessed using this model, *Pgr-cre Fst* cKO mice are unable to properly decidualize in response to an artificial decidual stimulus, supporting a role for uterine follistatin in regulating decidualization.

TGF β Family in the Uterus

Introduction

Because of the important roles TGF β family members play in development, knockout mice yield few clues into the importance of TGF β family signaling in the uterus. When a female infertility phenotype is observed, as in the inhibin β B or the ACVR2A knockout, the involvement of both ovarian and uterine defects confounds analysis of uterine phenotypes. For the interested reader, the phenotypes of mice with constitutive knockout of TGF β family signaling proteins are thoroughly reviewed in [Chang et al. \(2002\)](#).

Pgr-Cre

The advent of tissue-specific cKOs has allowed the roles of TGF β family members to be studied in the uterus. These cKO mice are created using two different genetic modifications. The first is replacing the coding region of one copy of a tissue-specific gene with a sequence encoding the Cre recombinase; this ensures that the Cre recombinase is expressed only in the tissues where the replaced gene would have been expressed. The second is modifying both alleles of the target gene to include sites, termed loxP sites, recognized by the Cre recombinase bracketing an essential region of the target gene; in any cell where the Cre recombinase is expressed, Cre-mediated recombination will excise the bracketed region, resulting in a non-functional allele. For studying the uterus, *Pgr-cre* has been invaluable. According to the original paper describing it, *Pgr-cre* is expressed postnatally in the anterior lobe of pituitary glands, granulosa cells of the postovulatory follicles, oviducts, and epithelium, and stroma of the uterus; however, cKO mice generated using *Pgr-cre* have shown a specific knockout in the uterus with excellent knockout in the epithelium and stroma (see studies described below).

BMP Signaling

The first TGF β family member studied using *Pgr-cre* was BMP2. In the mouse, BMP2 is expressed in the uterine stroma starting after embryo implantation and is strongly expressed in decidualizing stroma. Uterine cKO of *Bmp2* produces infertile females. *Bmp2* cKO females cannot form implantation sites because of an impaired decidual response to embryo attachment, demonstrating *Bmp2* is essential for decidualization.

Seeking to follow up on the role of BMP2 in decidualization, a uterine cKO of one of the type 2 receptors for BMP2, BMPR2, was generated. Intriguingly, although *Bmpr2* cKO mice are infertile, their phenotype differs from *Bmp2* cKO mice. *Bmpr2* cKO mice establish pregnancies with normal implantation sites until embryonic day 8, well past the beginning of decidualization at day 5 when pregnancies in *Bmp2* cKO mice fail. *Bmpr2* cKO mice can decidualize; however, their decidualization is defective and cannot support placentation because of poor vascularization and deficient recruitment of uterine natural killer cells. This suggests that whereas BMP2 may signal through BMPR2, the other type 2 receptors, ACVR2A or ACVR2B, may compensate for its absence during the initial days of decidualization.

The divergence between the uterine phenotypes of *Bmp2* and *Bmpr2* cKO mice suggests that ACVR2A and ACVR2B play an important role as ligands for BMP2 during decidualization; however, neither gene has yet been ablated using *Pgr-cre*. Knockout of *Acrv2b* is perinatal lethal, precluding any study of its role in female reproduction. Most *Acrv2a* knockout mice do survive to reproductive age and females are infertile; however, their infertility phenotype is caused by a severe reduction in pituitary production of follicle stimulating hormone (FSH) that causes dramatic defects in ovarian development and function, thus shedding little light on the roles of uterine ACVR2A during pregnancy.

In addition to BMPR2, two of the type 1 receptors used by BMP2—ALK2 and ALK3 have been conditionally ablated using *Pgr-cre*. *Alk2* cKO mice are sterile because of several defects during pregnancy. First, invasion of the embryo into the uterine epithelium and stroma is delayed after attachment, occurring a full day later in *Alk2* cKO mice. Second, decidualization is compromised with reduced proliferation and differentiation of stromal cells; however, the phenotype is less severe than that of the *Bmp2* cKO phenotype. Together, the delay in invasion and poor decidual reaction leave the uterus unable to support the implanted embryo and pregnancy terminates at 7.5dpc before placentation. Because *Alk2* cKO mice do not phenocopy *Bmp2* cKO mice, it is clear that BMP2 has an additional type 1 receptor partner during early pregnancy. *Alk3* cKO mice were generated to determine whether ALK3 is an essential partner for BMP2 in the uterus during pregnancy. *Alk3* cKO females are sterile; however, the cause of their infertility is distinct from the other uterine cKOs in the BMP signaling pathway. At 3.5dpc in a normal pregnancy, the uterine luminal epithelium is directed by progesterone signaling to stop proliferating and differentiate to facilitate embryo attachment and invasion. In *Alk3* cKO mice, this process fails and embryos are unable to attach to the apical surface of the luminal epithelium. Analysis of transcription factor binding in the uteri of wild-type females at 3.5dpc showed that SMAD4 and progesterone receptor (PR) bind the same region in the promoter of *Klf15*, a critical negative regulator of luminal epithelial proliferation, suggesting that BMP signaling cooperates with P4 signaling to promote uterine receptivity to embryo attachment. Because *Bmp2* cKO mice have normal embryo attachment, another BMP must be responsible for regulating uterine receptivity. The defect in uterine receptivity precluded observation of a natural decidual response, but artificial decidualization experiments show that ALK3 is required for proper decidualization, in line with its role as a receptor for BMP2.

Uterine BMP7 is also crucial for female reproduction. Indeed, conditional deletion of BMP7 with *Pgr-cre* (*Bmp7* cKO) resulted in female subfertility, with endometrial defects displayed during the window of implantation, such as epithelial proliferation, unopposed estrogen response and decreased progesterone signaling. Gene expression analysis of other BMPs during the window of implantation showed strong *Bmp5* expression in the luminal epithelium and stroma, suggesting that BMP5 compensates for the absence of BMP7 during implantation. To test this, *Bmp7* cKO were crossed to *Bmp5* KO mice to generate *Bmp7* cKO *Bmp5* KO mice. Fertility trials showed that the absence of BMP5 did not have additive effects on the fertility of *Bmp7* cKO mice, indicating that other BMP ligands may be involved in conferring endometrial receptivity. *Bmp7* cKO mice also demonstrated placental defects during mid-gestation, such as expansion of the trophoblast giant cells and absent spongiotrophoblast development. These defects indicate that BMP7 is crucial at two stages of pregnancy, during embryo implantation and later during placental development. An alternate explanation is that the absence of BMP7 during the window implantation perturbs normal embryonic and placental development that are manifested at later stages of gestation. Further studies are needed to establish the complete mechanism by which BMPs sensitize the endometrium for embryo receptivity as well as their roles in placental development.

SMADs

To date, no *Pgr-cre*-driven cKOs of the receptor SMADs or SMAD4 have been published. A recent paper, however, described the uterine phenotype of *Amhr2-cre* cKO of *Smad1/5/4*. *Amhr2-cre* acts in ovarian granulosa cells, the smooth muscle of the oviduct and uterus, and the uterine stroma. The *Smad1/5/4* triple cKO made using *Amhr2-cre* has defects in oviduct and uterine smooth muscle development, implantation failure, and defective decidualization. The phenotypes described differ notably from *Pgr-cre* models of BMP signaling. *Pgr-cre* *Alk3* cKO mice are not receptive to embryo attachment, whereas embryos can attach to the uteri of *Amhr2-cre* *Smad1/5/4* cKO mice. Additionally, whereas decidualization is defective in *Amhr2-cre* *Smad1/5/4* cKO mice, it is entirely absent in *Pgr-cre* *Bmp2* cKO mice. These differences, particularly with the *Pgr-cre* *Alk3* cKO mice, might be attributable to the lack of epithelial knockout in *Amhr2-cre* cKO; however, it could also be that *Amhr2-cre* is less effective than *Pgr-cre* in the uterine stroma. For example, *Amhr2-cre* cKO of COUP-TFII produces less severe phenotypes in the uterus than *Pgr-cre* cKO, despite the lack of COUP-TFII expression in the uterine epithelium. Alternatively, there could be underappreciated roles for non-SMAD TGF β family signaling in the uterus during early pregnancy.

TGF β Signaling

BMP-mediated signaling has been studied thoroughly in vivo; however, a few studies have examined the roles of TGF β - or activin/nodal-mediated signaling during pregnancy. Ablation of ALK5, the primary type 1 receptor for TGF β s, in the uterus causes nearly

complete infertility. ALK5 is expressed in response to embryo implantation at 4.5dpc and continues to be expressed during decidualization, declining after 6.5dpc. *Alk5* cKO mice show subtle abnormalities during implantation including delayed luminal closure, likely owing to the dysregulation of E2 and P4 signals observed at this time point. Although proliferation and differentiation occur normally during decidualization, uterine natural killer cells are not recruited and placentation is impaired with excessive trophoblast giant cells and a reduced placental labyrinth. The defects in placentation are likely responsible for spontaneous abortion later in pregnancy as mice with reduced numbers of uterine natural killer cells do not share this phenotype. Given the subtle phenotypes described in *Alk5* cKO mice, further in vivo studies are needed to determine the contribution of TGF β s to a successful pregnancy.

Nodal Signaling

Uterine cKO of *Nodal*, a member of the TGF β /activin group that signals through ACVR2A/B and ALK4/7, results in infertility because of reduced pregnancy rate, reduced survival to birth, and an ~80% rate of pre-term birth. The cause of the reduced pregnancy rate, measured as the percentage of mice with implantation sites at 5.5dpc, was not detailed, frustrating an assessment of the apparent function of nodal during early pregnancy. Pregnancy proceeds normally in *Nodal* cKO mice through decidualization until defects become apparent at 12.5dpc. Through a combination of reduced proliferation and apoptosis, the maternal decidua adjacent to the placenta regresses dramatically. Because the maternal decidua provides the blood supply and regulatory signals important for placental and embryonic development, it is likely that the excessive regression of the decidua is responsible for the reduced survival of pups to birth.

Knockout of ALK7, one of the type 1 receptors of activins and nodal, has no female reproductive phenotype, suggesting that it is dispensable during pregnancy. To investigate the role of the other activin/nodal type 1 receptor, ALK4, during pregnancy, a uterine cKO was generated using *Pgr-cre*. Intriguingly, *Alk4* cKO mice have a phenotype similar to *Nodal* cKO mice but it is not a phenocopy. *Alk4* cKO mice are subfertile, but do not experience preterm birth. Implantation and decidualization appear normal, but placental development is impaired. At 10.5dpc, there are excessive trophoblast giant cells and at 12.5dpc placentation is defective with reduced spongiotrophoblast and labyrinth. Because the labyrinth forms the site of nutrient exchange between mother and fetus, this defect in placentation likely accounts for the reduced survival rate of *Alk4* cKO pregnancies. The disparities between the *Nodal* and *Alk4* cKO phenotypes suggest that ALK7 likely plays a redundant role in transmitting nodal signals and that ALK4 may be transmitting activin signals to regulate placentation.

TGF β Family in the Ovary and Oviduct

Introduction

In addition to its important roles in the uterus, TGF β family signaling regulates ovarian function. Animal models have shown that TGF β family ligands including BMPs, GDFs, TGF β s, and activins regulate primordial germ cell development, folliculogenesis, and ovulation. Please note that our discussion excludes inhibins and activins.

Amhr2-Cre

Although global KO mice have provided important clues about the roles of the TGF β family in the ovary, critical developmental roles for many TGF β family members makes the engineering of tissue-specific cKOs essential. *Amhr2-cre* replaces one copy of *Amhr2* with the coding sequence for Cre recombinase. This allele expresses Cre in the granulosa cells of secondary and small antral follicles in the ovary and in the myometrium and stroma of the uterus. *Amhr2-cre* is not active in primordial or primary follicles, preventing analysis of the roles of TGF β family members in these early follicles using *Amhr2-cre* cKO.

BMP and GDF Signaling

Early studies of BMPs and GDFs using knockout mice quickly revealed important roles for BMP signaling in germ-cell development. *Bmp2* KO mice have fewer primordial germ cells (PGC) at 7.5 days of gestation and die between days 7 to 10.5 of gestation, preventing analysis beyond this early stage. *Bmp4* KO mice lack PGCs. A more severe PGC deficit in *Bmp2 Bmp4* heterozygous KO mice than in *Bmp4* heterozygous KO mice suggests that embryonic endoderm-expressed BMP2 and extraembryonic ectoderm-expressed BMP4 cooperate to regulate PGC generation. BMP8B is also critical for PGC generation as *Bmp8b* KO mice have reduced or absent PGCs; however, its role appears to be distinct from those of BMP2 and BMP4 because *Bmp8b Bmp4* heterozygous KO mice do not show a more severe phenotype than that of *Bmp4* heterozygous KO mice. In line with the important roles of BMP2/4/8B in PGC generation, *Alk2* KO mice have no primordial germ cells. Despite its critical roles, the mechanisms by which BMP signaling regulate PGC generation remain unclear.

Limited data suggests that BMP4 and BMP7 play a role in regulating the transition from primordial to primary follicles, which is marked by the shift of oocyte-supporting granulosa cells from flat to cuboidal structure. In rats, BMP4 is expressed by thecal cells starting in primary follicles. Treatment of rat ovaries in whole-organ in vitro cultures with BMP4 promotes the development of primary follicles and treatment with a BMP4-neutralizing antibody reduces the number of oocyte and primordial follicles. Treatment of adult rat ovaries with BMP7 by injection into the ovarian bursa increases the fraction of primary follicles and more

advanced follicles, while reducing primordial follicles; however, rat BMP7 is not expressed in the follicle until the secondary follicle stage in vivo, suggesting it may only support later stages of folliculogenesis.

Oocyte-derived BMP15 and GDF9 also play critical roles in folliculogenesis. *Bmp15* KO female mice are subfertile with incompletely penetrant defects in folliculogenesis and oocyte quality. *Gdf9* KO female mice are sterile because of a block in follicular development at the primary to secondary follicle transition. Sheep without functional BMP15 are infertile with a block at the primary stage in folliculogenesis, but heterozygotes for the inactivating mutation have an increased ovulation rate. Sheep without functional GDF9 show a similar phenotype, with infertility in homozygotes and excesses ovulation in heterozygotes. In humans, a dominant negative heterozygous nonsynonymous mutation in *BMP15* has been reported in women with hypergonadotrophic ovarian failure. Rare mutations in *GDF9* have been identified in families with a history of dizygotic twinning, supporting a role for GDF9 in regulating folliculogenesis or ovulation in women. Female mice with knockout of *Bmp15* and heterozygous knockout of *Gdf9* are infertile with defects in cumulus-cell development and expansion, suggesting that oocyte-produced BMP15 and GDF9 cooperate to promote folliculogenesis. In fact, BMP15 and GDF9, which are closely related paralogs, cooperate by forming heterodimers that regulate cumulus cell expansion. Mouse GDF9:BMP15 heterodimers are 10- to 30-fold more potent than mouse GDF9 homodimers in an in vitro granulosa cells cell assay, and human GDF9:BMP15 heterodimers are 1000- to 3000-fold more potent than human BMP15 homodimers in a human granulosa cell assay. BMP family heterodimers can achieve higher potency than homodimers because of the different receptor binding activities of each ligand allow heterodimers to interact more strongly with available type 1 and 2 receptors than homodimers. GDF9 binds the type 1 receptors ALK4/5/7, which signal through SMAD2/3, and BMP15 binds ALK1/2/3/6, which signal through SMAD1/5/8. Treatment with type 1 receptor kinase inhibitors demonstrates that GDF9:BMP15 heterodimers signal through ALK4, but not ALK6; however, ALK6-null mouse granulosa cells do not respond to GDF9:BMP15 heterodimer. Therefore, ALK4 and ALK6 are both required for heterodimer binding, but the type 2 receptor in the GDF9:BMP15 heterodimer-binding receptor complex, BMPR2, only phosphorylates and activates ALK4. In line with this, *Alk6* KO mice are infertile with defects in cumulus-cell expansion, similar to the phenotype of GDF9 KO mice, despite the lack of direct interaction between GDF9 and ALK6. Data from humans, sheep, and rodents diverge on the relative importance of BMP15 and GDF9 homodimers for cumulus granulosa cell regulation. Human and sheep granulosa cells do not respond to GDF9 homodimers in vitro and respond only mildly to BMP15 homodimers. In contrast, mouse and rat granulosa cells respond to GDF9 homodimers, but do not respond to BMP15 homodimers.

SMADs

Global and conditional *Amhr2-cre* knockouts of SMAD proteins have informed our understanding of the roles of TGF β family signaling in PGC development, follicle development, and cancer prevention. In line with the defects in PGC development seen in *Bmp2*, *Bmp4*, and *Bmp8b* KO mice, knockouts of their downstream receptor SMADs, SMAD1 and SMAD5, have fewer PGCs and SMAD4 cKO in the early mouse epiblast precludes PGC development. PGC development is not SMAD8-dependent, as no PGC deficits are seen in *Smad8* KO mice.

Amhr2-cre cKO of *Smad1* or *Smad5* are fertile without ovarian phenotypes; however, double *Smad1/5* cKO mice are infertile and develop metastatic granulosa cell tumors. Intriguingly, knockout of inhibin α , an inhibitor of activin signaling through SMAD2/3, also enables development of granulosa cell tumors. Gene and protein expression analysis reveals that granulosa-cell tumors in both *Smad1/5* cKO mice and inhibin α KO mice are driven by excessive activin signaling, supporting a model in which development of granulosa-cell tumors is caused by disruption of an antagonistic equilibrium between BMP-SMAD1/5 and activin-SMAD2/3 signaling. In this instance, BMP-SMAD1/5 signaling suppresses tumorigenesis while activin-SMAD2/3 signaling promotes it. Signaling through SMAD8 does not appear to play a significant role in suppressing tumorigenesis, as *Smad8* cKO, *Smad1/8* cKO, and *Smad5/8* cKO mice have no reproductive phenotypes and *Smad1/5/8* cKO phenocopies *Smad1/5* cKO.

Smad3 KO mice are subfertile with impaired follicle growth, increased atresia, and defects in differentiation; however, the contribution of ovarian knockout is unclear as hormonal imbalances caused by pituitary loss of SMAD3 confound analysis. Neither *Smad2* nor *Smad3* *Amhr2-cre* cKO mice have female fertility defects, whereas double *Smad2/3* cKO mice are subfertile with disrupted follicular development, ovulation, and cumulus-cell expansion. At 3 and 8 months of age, *Smad2/3* cKO mice show significantly fewer antral follicles and an accumulation of zone pellucida remnants, indicating follicular atresia owing to oocyte loss.

Smad4 *Amhr2-cre* cKO mice have a phenotype distinct from either *Smad1/5* or *Smad2/3* cKO mice. *Smad4* cKO causes subfertility with decreasing fertility over time characterized by multiple defects in folliculogenesis. In response to superovulation with equine chorionic gonadotrophin, antral follicles in *Smad4* cKO mice undergo premature luteinization. Cumulus-cell expansion is also abnormal or absent in COCs isolated from *Smad4* cKO mice after superovulation. Supporting the hypothesis that granulosa cell tumors in *Smad1/5* cKO mice arise from excess activin signaling through *Smad2/3*, *Smad4* cKO mice do not develop granulosa cells tumors.

ALK3 and ALK6

Knockout of *Alk6* (*Bmpr1b*) in mice causes female infertility because of a failure of cumulus cell expansion. Notably, *Amhr2-cre* cKO of *Alk3* reveals a distinct function from ALK6, despite their shared ligand partners and downstream receptor SMADs; *Alk3* cKO females are subfertile with reduced spontaneous ovulation. Females with *Amhr2-cre* conditional double knockout of *Alk3/6* develop

granulosa cell tumors, phenocopying *Smad1/5* cKO and *inhibin α* KO mice. In sheep, an ALK6 kinase domain missense mutation increases ovulation rate and litter size.

TGF β Signaling

The roles of TGF β s in the ovary remain unclear. Mouse knockouts for TGF β 1, TGF β 2, and TGF β 3 have been produced and are perinatal lethal, permitting only prenatal and perinatal phenotypes to be assessed. TGF β 1 and TGF β 3 KO mice show no ovarian defects at birth. TGF β 2 KO mice have an increased number of germ cells in the ovary, suggesting that TGF β 2 may play a role in regulating PGC development. However, data in various adult models is muddled. For example, rat thecal cells in preantral and antral follicles express TGF β 1 and TGF β 2, preantral expression has been reported in sheep, and in vitro evidence suggests a role for TGF β s in regulating granulosa cells in cattle and humans. However, the absence of ovarian phenotypes in *Amhr2-cre* cKO of ALK5, the primary type 1 receptor for TGF β s, indicates that TGF β signaling through ALK5 is not essential for normal mouse ovarian function. *Alk5* cKO mice do suffer from developmental defects of the oviduct and uterus, particularly in smooth muscle development, but which TGF β family ligands signal through ALK5 to regulate oviduct and uterine development remains unclear.

Summary

The expression of ligands, receptors, and downstream effectors of the TGF β family are carefully coordinated throughout life, participating critically in development and adult tissue function. Data from genetic mouse models have demonstrated that TGF β family signaling in the uterus and ovaries is essential in female reproduction. Although much progress has been made towards characterizing the roles of TGF β family signaling in female reproduction, the complexity of ligand/receptor combinations and the context-dependent nature of responses to TGF β family signals leave open numerous avenues for future study.

Introduction

What is AMH and Its Source in Females

AMH is a dimeric glycoprotein and a member of the transforming growth factor β (TGF β) superfamily of growth and differentiation factors. It is produced by Sertoli cells of the testes in the male and by granulosa cells of healthy, growing ovarian follicles in females (Visser et al., 2006).

AMH Mechanism of Action

Like other TGF β family members, AMH signals through a receptor complex consisting of two type I and two type II receptors. AMH binding causes type II receptor mediated phosphorylation and activation of the type I receptor, which in turn activates the SMAD pathway. Receptor-activated SMADs then interact with SMAD₄ and translocate to the nucleus to modify target gene expression.

The type II AMH receptor (AMHRII) is specific for AMH, whereas there are three type I AMH receptors (ACVR₁, BMPR_{1A}, and BMPR_{1B}) that are shared with bone morphogenetic proteins (BMPs), which are also members of the TGF β family. AMHRII mRNA is expressed in granulosa cells of small growing follicles. Type I AMH receptors mRNA is expressed in oocytes, granulosa, and theca cells at different stages of follicular development (reviewed in Visser et al., 2006).

AMH Functions

Mammals, such as human beings, cattle, swine, and sheep are born with a finite number of morphologically healthy follicles and oocytes in the ovaries (the ovarian reserve) that dwindle rapidly during aging and are never replenished. Follicular recruitment starts soon after birth and is continuous throughout life. In female AMH null mice, follicles are recruited at a faster rate, resulting in an exhausted pool of primordial follicles at a younger age compared to wild-type controls. Also, AMH inhibits primordial follicle assembly and decreases the initial primordial follicular pool size in a rat ovarian organ culture. Similarly, AMH inhibited the initiation of follicle growth in cultured pieces of human ovaries (reviewed in Dewailly et al., 2014) and recently, AMH was shown to inhibit follicular activation and attenuate the growth of primary follicles in bovine fetal ovarian cortical pieces in vitro (Yang et al., 2017). These findings indicate that AMH acts as a brake on follicular development in humans, rodents and in cattle, inhibiting primordial follicular growth from the ovarian reserve and avoiding its premature exhaustion.

AMH is also believed to reduce the responsiveness of preantral and small antral follicles to FSH, modulating follicular development. In cultured human granulosa cells, AMH inhibited FSH-induced aromatase mRNA and protein expression and estradiol production and AMH inhibited FSH effects on follicular growth in women and mice (reviewed in Dewailly et al., 2014).

Regulation of AMH Secretion

AMH secretion changes as the ovarian follicle develops; AMH expression starts in primary follicles, reaches its highest level in preantral and small antral follicles, whereas it then decreases as the selected, FSH-dependent follicle progresses toward the preovulatory stage and is absent in atretic follicles. This pattern of expression was first assessed in rodents and subsequently in women, cattle and sheep. Nevertheless cumulus cells of preovulatory follicles continue to express AMH in women and mice (reviewed by Monniaux et al., 2012).

AMH production is stimulated by the oocyte: evidence indicates that BMPs, such as BMP4, BMP6, and BMP15 originating from oocyte and theca cells, stimulate AMH mRNA expression by granulosa cells. On the contrary, FSH appears to have an inhibitory effect on AMH secretion, albeit still poorly understood. FSH decreased AMH mRNA expression in rat and cattle, but not in sheep (reviewed by Monniaux et al., 2012); however, FSH enhanced AMH gene expression and protein secretion in bovine granulosa cells in vitro at low concentrations, but inhibited them at higher concentrations (Scheetz et al., 2012). In summary, the regulation of AMH secretion by FSH is complex and the mechanism that regulates AMH secretion is unclear.

Alterations in Circulating AMH Concentrations From Birth to Puberty

In healthy women, peripheral AMH concentrations change throughout life. A marked postnatal rise in AMH concentrations was reported in girls, with higher AMH at 3 months of age compared to those at birth, followed by a decrease at 12 months. This peak in early infancy was interpreted as an ovarian response to prevent FSH-induced follicle growth at a time when further differentiation of follicles would be inappropriate (Hagen et al., 2010).

Fig. 1 Circulating AMH concentrations (ng/mL) in dairy ($n = 9$) and cross bred beef ($n = 13$) female calves. Results of ANOVA indicated that mean AMH concentrations were similar between dairy and beef calves ($P = 0.11$), but varied with time ($P < 0.01$) (Mossa et al., 2017).

Several studies report that serum AMH levels rise steadily during childhood with greatest levels at around 15–18 years, but are stable during early adulthood (18–25 years). This pattern has been assessed in Caucasian and Chinese women, and may suggest that ethnicity does not have an impact on age-related AMH variations in women (Hagen et al., 2010). Nevertheless, the mechanisms responsible for the increase in AMH concentrations during childhood in girls remain to be elucidated.

We conducted a study to illustrate the variations of AMH from birth to puberty in Holstein female calves (Mossa et al., 2017). Results depicted in Fig. 1 show that AMH concentrations increase during the first 2 months of age, decrease at 5 and are stable at 8–9 months of age, around the time of first ovulation. We also described a similar pattern in beef calves (Mossa et al., 2017). In Maine-Anjou beef heifers, plasma AMH concentrations increased rapidly between 1 and 3 months of age, remained high at 6 months of age then declined slowly until 12 months of age, which corresponds to the age of ovulation for this breed (Monniaux et al., 2012). These findings are supported by results from others indicating that 3- to 4-month old calves have greater AMH levels compared to young adult heifers in both Holstein (14–16 months) and *Bos indicus* Nelore (18–24 months) cattle (reviewed in Mossa et al., 2017). In summary, AMH concentrations increase in the first months of life and decrease before puberty in cattle, like women, but the timing of such fluctuations may vary among breeds and genetic groups. Prepubertal heifers experience waves of antral follicular growth like adult cattle and number of follicles increases from 2 to 14 weeks of age (Evans et al., 1994). Thus, it is plausible that the variations in AMH concentrations observed before puberty are reflective of changes in growth patterns of small antral follicles. Another possible explanation is that prepubertal variations in circulating AMH concentrations are due to changes in the ability of granulosa cells to secrete AMH.

Alterations in Circulating AMH Concentrations during Estrous and Menstrual Cycles

In women, AMH peripheral concentrations remain relatively constant during the menstrual cycle (La Marca et al., 2009). For example, in a study conducted on young (aged 19–35 years) normo-ovulatory women, the fluctuations of serum AMH levels were not significant either when aligned to day of menstrual cycle or to day of ovulation. Also, another study reported that AMH concentrations were not different within individual young women (aged 24–40) across a number of up to four consecutive menstrual cycles, ranging between 5.7 and 6.0 ng/mL (van Disseldorp et al., 2010). The limited variation in AMH peripheral concentration during the menstrual cycle indicates that AMH serum levels are not affected by dominant follicle growth during the late follicular phase of the normal menstrual cycle despite the finding that AMH expression declines in large follicles. These findings taken together imply that a single measurement of AMH is predictive of circulating AMH concentration during the menstrual cycle. The static nature of AMH concentrations enhances its clinical usefulness for example to assess response to ovarian stimulation protocols during ART compared with other currently available clinical markers of reproductive function, such as inhibin B, estradiol (E_2), and FSH, which are all menstrual cycle dependent.

Evidence is also accumulating that AMH concentration varies minimally during estrous cycles in cattle. For example, we reported that a single AMH measurement in young adult beef heifers was highly correlated ($r = 0.97$) with the average for multiple AMH measurements during different days of the same or multiple estrous cycles (Ireland et al., 2011). In Holstein cows, AMH varied

minimally during the same estrous cycle and on different days of two estrous cycles (reviewed in [Mossa et al., 2017](#)). Taken together these findings illustrate the static nature of AMH during the estrous cycle and its repeatability across multiple estrous cycles in cattle.

Conversely, in mice serum AMH levels were increased at estrus and gradually declined to basal levels during the following days of the cycle ([Visser et al., 2006](#)). Such differences between mice compared with women and cattle may be explained by species differences in the dynamics of follicular growth and associated AMH secretion during reproductive cycles.

Correlation of Circulating AMH Concentrations With Antral Follicle Count, Size of the Ovarian Reserve (All Healthy Follicles), and Aging

In women, antral follicle count (AFC) is defined as the number of follicles measuring 2–10 mm in diameter and is assessed by transvaginal ultrasound. AFC is proportionally related to the size of the ovarian reserve ([La Marca et al., 2009](#)). Similar to AFC, circulating AMH is a marker of the size of the ovarian follicular reserve in humans and in mice. Several studies report that AFC and serum AMH are strongly ($r = 0.74$) to moderately ($r = 0.57$ – 0.47) positively associated. For example, when AFC and AMH were repeatedly measured during a menstrual cycle, the moderate fluctuations in serum AMH concentration paralleled the variation in number of follicles 2–8 mm in diameter ([Depmann et al., 2016b](#)). This positive correlation between AFC and AMH can be explained by the AMH production by the small antral follicles that are also detected by ultrasonography. Both AFC and AMH are often used independently or jointly to estimate the size of the ovarian reserve and to predict the ovarian response to hormonal stimulation during ART ([La Marca et al., 2009](#)).

A high positive correlation was observed between the variation in AMH, AFC and histological determination of total number of morphologically healthy follicles and oocytes in ovaries of young adult cattle ([Ireland et al., 2008](#)). In beef heifers, circulating AMH concentrations were approximately six- and twofold greater in animals with high (≥ 25 follicles, ≥ 3 mm in diameter) or intermediate (16–24 follicles) compared with a low (≤ 15 follicles) AFC during follicular waves ([Fig. 2](#), left panel). Also, the overall average AMH concentration during ovulatory follicular waves per animal was highly correlated ($r = 0.88$; [Fig. 2](#), right panel) with average peak AFC during the two or three waves of an estrous cycle ([Ireland et al., 2008](#)). In another study, AMH plasma concentrations were highly positively correlated with the numbers of 3–7 mm antral follicles detected by ovarian ultrasonography in primiparous dairy cattle ([Rico et al., 2009](#)). Also, a positive association was detected between the antral follicle population and circulating AMH concentrations in Murrah (*Bubalus bubalus*), Holstein (*Bos taurus*), and Gyr (*Bos indicus*) heifers ([Mossa et al., 2017](#)). It can be

Fig. 2 Alterations in circulating AMH concentrations during ovulatory follicular waves in cattle. Serial ovarian ultrasonography was used to identify animals with a consistently low (≤ 15 follicles ≥ 3 mm in diameter per wave, $n = 4$ animals), intermediate (16–24 follicles, $n = 8$), or high (≥ 25 follicles, $n = 4$ animals) peak AFC during ovarian follicular waves. Prostaglandin $F_{2\alpha}$ then was used to synchronize estrus, and ovarian ultrasonography was used to reconfirm that animals were correctly identified and to determine day of ovulation. Blood samples were taken daily at 1100 h beginning on Day 6 of the estrous cycle and ending 1 day after ovulation. Serum samples obtained 6–8 days preceding ovulation, which corresponded with ovulatory follicular waves, and on the day of ovulation were analyzed for AMH concentrations. In the left graph, data for each animal were aligned relative to day of ovulation, and data are plotted based on results of linear regression analysis. Each point represents the mean $\pm$ SEM for four or eight animals. In the right graph, average AMH concentration per animal was plotted relative to the average peak number of antral follicles per wave during the estrous cycle for each animal; r = correlation coefficient and n = total number of animals ([Ireland et al., 2008](#)).

concluded, therefore, that AMH and AFC are positively correlated in cattle and both AFC and AMH can be used interchangeably and reliably to estimate total number of morphologically healthy follicles and oocytes in the ovaries of an individual.

Diagnostic Use of AMH to Predict Fertility, Age at Menopause and Response to ART

Predict Fertility

In cattle, in our recent work, AMH concentrations were determined in young adult Holstein heifers at 11–12 months of age and a variety of fertility measurements made before and after calving in the same individuals. Results showed that conception rates to first artificial insemination (AI), services per conception and days open after calving until pregnant were similar among individuals in the different AMH quartiles before calving and during the first, second and third lactations. However, the quartile (Q) of cows with the lowest AMH concentrations (Q1) as heifers tended ($P < 0.10$) to be lower at each lactation and had the lowest overall average for total percentage pregnant compared with cows in Q2 or Q3 but not Q4 AMH quartiles (Jimenez-Krassel et al., 2015). These findings contrast somewhat with our other study that examined fertility in dairy cows (up to eight parities) with low, intermediate or high AFC and presumably corresponding differences in AMH concentrations. In this study, dairy cows with a low AFC had a lower conception rate to first AI, greater number of AI to conceive and higher calving interval compared with cows with an intermediate or high AFC (Mossa et al., 2012). Like our finding for dairy cows with low AMH as a heifer (Jimenez-Krassel et al., 2015) overall pregnancy rate was lower for the dairy cows with a low compared with a high AFC (Mossa et al., 2012). Another study shows that dairy cows with high AMH had greater pregnancy rates and lower incidence of pregnancy loss between days 30 and 65 of gestation. Lower fertility for cattle with a relatively low AFC is further supported by evidence of lower pregnancy rates in beef heifers with a low vs. a higher AFC and by a study showing that lactating cows with a low AFC had a longer interval from calving to conception and lower pregnancy rates than cows with a high AFC (reviewed in Mossa et al., 2017).

The reasons for the differences between some fertility measurements in the studies that classified cattle based on AMH or AFC are unknown but likely caused by relatively small numbers of cattle in AMH quartiles and some AFC groups coupled with mixed ages of cows in AFC groups. In addition, cross-sectional studies using older cows may be biased by previous removal (culling) of individuals from the herd with a relatively low AFC or AMH. Nevertheless, combined results (Mossa et al., 2017) imply that fertility is suboptimal in cows with low AMH concentrations as heifers and in cows with low AMH or a low AFC compared with herd mates with higher AMH concentrations or a higher AFC.

Age at Menopause

In women, the size of the ovarian reserve declines with age until there are too few follicles to sustain menstrual activity and menopause (final menstrual period) is reached. Menopause occurs at a mean age of 51 years when the ovarian reserve drops to approximately 1000 follicles, but the age at which natural menopause occurs varies considerably between 40 and 60 years (te Velde & Pearson, 2002). Similarly, the rate of decline of the ovarian reserve varies significantly among individuals and the high variability of age at menopause is believed to be caused by the high variation in the number of ovarian follicles and oocytes at birth. Since AMH is a marker of the ovarian reserve, it is considered a promising marker to predict age at natural menopause. So far, six studies showed that AMH concentration is predictive of age at natural menopause (hazard ratio, 5.6–9.2) (Depmann et al., 2016), but long-term studies on large numbers of women are lacking.

Response to ART

Assisted reproductive technology (ART), which includes hormonal stimulation, AI, in vitro fertilization and surrogacy, is used in both women and cattle. Ovarian stimulation consists of the artificial increase of FSH concentration that leads to the simultaneous growth of several follicles. The oocytes can be recovered from the stimulated follicles and fertilized in vitro or they can be allowed to ovulate (superovulation) and fertilized in vivo. In women oocytes are usually collected before ovulation, whereas in cattle superovulation is commonly followed by AI and the nonsurgical recovery of the embryos. The ovarian response to hormonal stimulation varies greatly among individuals in both women and cattle; such responsiveness is negatively associated with aging and growing evidence indicates that it can be predicted by measuring serum AMH concentrations (La Marca et al., 2009).

In women AMH correlates strongly with the number of oocytes retrieved following ovarian stimulation for IVF (La Marca et al., 2009), hence it is now widely used to assess the size of the ovarian reserve before assisted conception. Women with high AMH are likely to respond excessively to exogenous gonadotrophins (Dewailly et al., 2014), leading to a serious condition named ovarian hyperstimulation syndrome (OHSS), thus their treatment strategy can be modified by using a less intense ovarian stimulation regime. Conversely women with a low AMH are likely to respond poorly to stimulation with consequently a low chance of pregnancy (Dewailly et al., 2014) and their expectations can be managed appropriately, reducing the financial and emotional burden on couples seeking ART treatment.

Evidence is now growing to support the use of AMH as a predictor of the responsiveness to ovarian stimulatory treatment in agricultural species. In primiparous dairy cows, AMH concentrations before the superovulatory treatment were positively correlated with the number of follicles before treatment and with the numbers of large follicles and corpora lutea (CL) after treatment (Rico et al., 2009). In nonlactating Holstein cows, plasma AMH concentrations before gonadotropin treatments were highly correlated

with the numbers of large follicles and oocytes recovered at ovum pick up (OPU), as well as with the number of large follicles at estrus and the number of embryos collected from multiple ovulation and embryo transfer protocols. Further, in Japanese Black beef cattle, AMH concentrations were positively correlated with the number of follicles, number of oocytes/embryos recovered, fertilized embryos and transferable embryos. In lactating Holstein cows, AMH concentrations for each individual cow were correlated with superovulation response (number of CL on the day of the flush), total oocytes collected and total transferable embryos. Also, when cows were classified into quartiles of circulating AMH, Q4 cows had a > 2-fold greater response to superovulation including embryo production compared with cows in other quartiles (Mossa et al., 2017). In addition, a positive correlation existed between AMH with OPU and in vitro embryo production in Holstein, beef (Korean Hanwoo) and *Bos indicus* (Zebu) cattle (Mossa et al., 2017).

Summary and Conclusion

Evidence from studies conducted in women, cattle and rodents indicates that AMH circulating concentration (1) increases in the first months of life and then decreases until puberty; (2) is repeatable in the same or multiple estrous/menstrual cycles within individuals; (3) is positively correlated with AFC; (4) is a reliable indicator of the total number of healthy follicles and oocytes; (5) is positively associated with measures of fertility (women and cattle: response to ovarian stimulation; cattle: pregnancy rate, herd longevity); (6) is a promising candidate to predict age at menopause. Taken together, these findings support the potential utility of AMH measurement in human ART and in agricultural species as a predictor of fertility. However, uncertainty still exists concerning AMH mechanism of action and regulation of secretion. Cattle may be used as a valid animal model to further corroborate the association between AMH and fertility in mammals.

Glossary

Central-drive hypothesis of puberty It postulates that the initiation of puberty emerges from changes in the activity of the central pathways controlling GnRH neurons. According to this concept, in addition to sex steroid-mediated negative feedback, a central inhibitory system restrains GnRH secretion at early stages of pubertal development. At the onset of puberty, this inhibitory tone is vanished or is dominated by a central stimulatory system. For further details, see Fig. 1.

Epigenetics Inheritable information that is not encoded by the nucleotide sequence of a given gene. Epigenetic regulatory mechanisms include DNA methylation, histone modifications, and microRNAs (miRNA).

Gonadostat hypothesis of puberty It proposes that the onset of puberty results from a developmental change in the sensitivity of the hypothalamic-pituitary unit to the inhibitory feedback action of sex steroids. This sensitivity gradually decreases when puberty approaches, resulting in an increased gonadotropin-releasing hormone (GnRH) secretion that leads to the initiation of puberty.

Kisspeptins Family of structurally related RF-amide peptides, encoded by the KISS1/Kiss1 gene, that act through binding and subsequent activation of the G protein-coupled receptor, Gpr54, which is also termed kisspeptin receptor or Kiss1R.

Kisspeptins have emerged as important gatekeepers of key aspects of reproductive maturation and function, including sexual differentiation of the brain, puberty onset, adult regulation of gonadotropin secretion, and metabolic control of fertility.

KNDy neurons Subset of Kisspeptin neurons located in the hypothalamic arcuate (ARC) nucleus that co-express Neurokinin B (NKB) and Dynorphin A (Dyn) (acronym made using the underlined words). The KNDy hypothesis sets the notion that the dynamic release of kisspeptin from ARC kisspeptin neurons onto GnRH neurons is controlled by the opposite actions of NKB, which are mostly stimulatory, and Dyn, which are mainly of inhibitory nature.

Leptin Adipose hormone that is encoded by the Lep gene. Leptin is released to circulation in proportion to the size of fat stores. In terms of metabolic control, leptin acts as an anorexigenic, and thermogenic factor at the hypothalamus to adjust energy requirements, fat reserves, and food intake. In the context of reproductive function, leptin operates as an essential gatekeeper of puberty and fertility in mammals.

Makorin 3 (MKRN3) Intronless, maternally imprinted gene located on human chromosome 15q11–13. This gene encodes a protein with a conserved RING finger domain and several ZNF motifs with predicted ubiquitin-protein isopeptide ligase E3 activity. MKRN3 has been recently proposed as a potential repressor of puberty onset.

MicroRNAs (miRNAs) Small, noncoding RNAs that can modulate (mainly repress) gene/protein expression, mainly by interaction with seed regions at the 3' untranslated region (3'-UTR) of target genes, thereby promoting mRNA degradation or preventing protein translation.

Polycomb group (PcG) Family of epigenetic regulators of transcription that modify histones (and other proteins) and silence target genes. They function within multiprotein complexes, called Polycomb repressive complexes (PRCs), which include PRC1, PRC2, and PhoRC. Cbx7 and Eed, members of PRC1 and PRC2, respectively, have been shown to be essential components of a novel epigenetic mechanism of transcriptional repression involved in the central control of female puberty.

Introduction

Puberty is a fascinating developmental period that culminates with the attainment of reproductive capacity (Parent et al., 2003). This maturational phenomenon starts to be shaped at early stages of development and involves a complex series of morphological, physiological, behavioral, and psychological changes that allows the acquisition of a complete adult phenotype (Parent et al., 2003). The timing of puberty critically depends on the interplay between genetic and environmental factors (Parent et al., 2003). Indeed, when the dynamic interaction between these two elements is inappropriate, maturation of the reproductive axis is affected, and the timing of puberty is altered. Hence, in addition to its physiological dimension as an essential developmental process, puberty may serve as a biological sensor (and eventual sentinel) for perturbations of gene–environment interactions during pre- and postnatal development.

Assessment of Pubertal Development: External Markers

The assessment of pubertal maturation is particularly relevant in clinical practice and relies on specific changes related to body growth and composition, as well as the development of secondary sexual characteristics. Marshall and Tanner were the first to provide a standard frame of reference for such assessment in both girls and boys. This reference method, known as Tanner scale, allows classifying pubertal development into five continuum stages (from infantile to adult) on the basis of somatic changes in breast, pubic hair, and genital development (Marshall and Tanner, 1969, 1970). In girls, the first sign of puberty initiation is often thelarche (that typically occurs at Tanner stage II), which consists of the onset of breast bud development (Snyder, 2016). This phenomenon is usually followed by pubarche; a process that involves the development of axillary and pubic hair and depends on an increase in adrenal androgen production—termed adrenarche—(Bordini and Rosenfield, 2011). Approximately 2 or 2.5 years after thelarche (at Tanner stage III or, more often, at IV) typically occurs menarche, which represents the first menstrual cycle and, eventually, the final marker of puberty completion in girls (Snyder, 2016).

The study of the mechanistic basis of puberty and its eventual alterations also requires the precise assessment of pubertal maturation in laboratory rodents (i.e., rats and mice), which are widely used in biomedical research. External signs of puberty onset conventionally assessed in female rodents are: (i) the complete canalization of the vagina (i.e., vaginal opening; VO); (ii) the first appearance of cornified epithelial cells in the vagina (i.e., first vaginal estrus; FE); (iii) and the presence of a vaginal plug (VP) after mating (Gaytan et al., 2017; Ojeda and Skinner, 2006). However, it is worth to note that those pubertal markers show relevant differences between rats and mice, especially in terms of reliability. For instance, VO and FE are tightly coupled with the first ovulation in female rats, and consequently, the age of VO is a reliable marker of puberty onset for this species (Ojeda and Skinner, 2006). In contrast, VO and FE are not always immediately followed by first ovulation in mice, which the value of these external pubertal markers for accurate detection of completion of puberty in female mice. In this species, postmating VP seems to be the most accurate external sign of first ovulation (Safrański et al., 1993).

Trends in Pubertal Timing

Recent epidemiological studies conducted in different countries have documented a downward trend in the age of puberty in girls. In the United States, a higher prevalence of thelarche among girls at ages 7 and 8 has been detected when compared with epidemiological data obtained a decade earlier (Biro et al., 2010). In the same vein, a European study conducted over 15 years (1990–2006) in Copenhagen has reported an advancement of approximately 1 year (from 10.88 to 9.86 years) in the onset of breast development in two cohorts of girls (Akslaede et al., 2009b). This phenomenon has also been documented in China, where a recent cross-sectional study of over 20,000 girls has detected an earlier onset of thelarche (Ma et al., 2009).

Although the above epidemiological data requires further validation and demonstration in other populations, this trend toward an earlier puberty onset in girls has caused considerable concerns among scientists and lay public. This is mainly due to the potential health issues associated with this pubertal phenotype, which includes increased risks for up to 48 adverse outcomes across a range of cancer, cardiovascular, gynecological, metabolic, musculoskeletal, and neurocognitive categories (Day et al., 2015; Elks et al., 2013; Velie et al., 2005). The higher prevalence of childhood obesity and the increased exposure to endocrine disruptors have been suggested as relevant factors for this trend in pubertal timing (Akslaede et al., 2009a,b).

Neuroendocrinology of Female Puberty

Female puberty involves the full activation of the so-called hypothalamic-pituitary-ovarian (HPO) axis, which is responsible for the completion of ovarian development and the attainment of sexual phenotypic maturity (Tena-Sempere, 2012; Tena-Sempere and Huhtaniemi, 2003). The function of this intricate neurohormonal system depends primarily on the coordinated interaction of three major groups of signals: (i) the decapeptide gonadotropin-releasing hormone (GnRH), which is synthesized and released in a pulsatile manner by a scarce group of hypothalamic neurons; (ii) the gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which are produced and secreted by gonadotropic cells of the anterior pituitary; and (iii) the sex steroids, which are generated along with fertilizable gametes and specific regulatory peptides by the ovaries. These components are connected each other via feed-forward and feedback loops, thus facilitating its homeostatic regulation. Furthermore, these regulatory circuits are also sensitive to other endogenous factors and exogenous cues, which contribute to its dynamic modulation (Tena-Sempere and Huhtaniemi, 2003).

Mechanisms for the Onset of Puberty: The Essential Role of GnRH Neurons

In female mammals, it is well known that the initiation of puberty requires a sustained increase in the pulsatile release of GnRH from the hypothalamus (Ojeda and Skinner, 2006). However, it is still a great mystery how such increase occurs. For several decades, it was thought that the increase in the neurosecretory activity of GnRH neurons resulted from a decreased sensitivity of the hypothalamic-pituitary unit to the inhibitory feedback action of ovarian estrogen (Gore, 2002; Rapisarda et al., 1983). Following this assumption, named “gonadostat” hypothesis, the removal of the immature ovary and (eventually) estrogen should result in an increased GnRH/LH response, while estrogen replacement after ovariectomy should cause a suppression of GnRH/LH secretion at prepubertal developmental stages but not at the onset of puberty. In good agreement with this hypothesis, initial studies in female rats demonstrated that ovariectomy (OVX) followed by estrogen replacement suppressed LH secretion at prepubertal stages of development, but not at the time when VO occurs (Steele and Weisz, 1974). However, further evidence brought the above assumption into question. Thus, studies conducted in female rats demonstrated that (i) the loss of responsiveness to the estrogen-negative feedback takes place after, but not before, the first ovulation (Andrews et al., 1981) and (ii) the effectiveness of estrogen in suppressing gonadotropin secretion only changes slightly before puberty (Kawagoe and Hiroi, 1983). In the same vein, results obtained in female rhesus monkeys and humans revealed that GnRH/LH secretion is highly sensitive to the inhibitory actions of estrogen at the time of puberty, that is, when gonadotropin levels are already increasing (Chongthammakun et al., 1993; Maruca et al., 1983). Overall, the above data suggest that the pubertal increase in GnRH/LH secretion may primarily be an ovarian-independent phenomenon in females, especially in humans.

Compelling evidence supports that the increase in the pulsatile GnRH secretion responsible for the onset of female puberty may emerge from changes in the activity of the central pathways controlling GnRH neurons (Ojeda and Skinner, 2006). According to this assumption, known as “central drive” hypothesis (see Fig. 1), the intrinsic oscillatory nature of GnRH neurons along with the wide array of afferents that integrate the so-called GnRH pulse generator, are the key components for the pubertal activation of GnRH neurosecretory activity (Ojeda and Skinner, 2006). The latter is based on the following pieces of evidence: (i) GnRH neurons, which migrate from the olfactory placode to the basal forebrain during embryonic development, reach their final destination (hypothalamus) and project their axons to the median eminence before birth (Jennes, 1989; Prevot, 2015); (ii) the secretory activity of GnRH neurons is prematurely enhanced by the electrical stimulation of the hypothalamus (Claypool et al., 1990; Meijs-Roelofs, 1972); (iii) the dendritic morphology of GnRH neurons changes substantially during the juvenile–pubertal transition, with increased numbers of spines and dendritic rearrangements as puberty approaches (Herbison, 2016); and (iv) GnRH neurons are sensitive to inhibiting and stimulating signals of GnRH release before the onset of puberty (Ojeda et al., 2006b). Considering the above data, it has been proposed that the pubertal activation of GnRH neurons is brought about by coordinated changes in trans-synaptic and glial inputs to the GnRH neuronal network, consisting of a reduction of inhibitory influences and an increase in stimulatory signals (Ojeda et al., 2006b).

The inhibitory trans-synaptic circuitry controlling GnRH release is mostly composed of neurons that produce γ -aminobutyric acid (GABA), endogenous opioids, and eventually RFamide-related peptides (RFRP) (Lomniczi et al., 2013b). GABAergic neurons can modulate GnRH release through indirect actions on neurons connected to the GnRH neuronal network (Ojeda et al., 2006a) or direct actions mediated by the activation of GABA-A receptors on GnRH neurons (Moenter and DeFazio, 2005); it must be noted, however, that direct depolarizing actions of GABA on GnRH neurons have repeatedly been reported. Opiatergic neurons repress GnRH neuronal activity through different peptides acting on different receptors (Fabbri et al., 1989). These actions may be exerted either on GnRH neurons (Dudas and Merchenthaler, 2006) or on neurons involved in the stimulatory control of the GnRH neuronal network (Navarro et al., 2009). RFRP is the mammalian ortholog of the gonadotropin-inhibitory hormone (GnIH), originally described in birds (Leon and Tena-Sempere, 2015). RFRP neurons produce two different peptides, RFRP1 and RFRP3, which can be recognized by a high-affinity receptor, named NPFF1R or GPR147, and a low-affinity receptor, termed NPFFR2 or GPR74 (Leon and Tena-Sempere, 2015). The fact that NPFF1R is expressed in GnRH neurons suggests that RFRP neurons may directly suppress GnRH secretion through this receptor (Ducret et al., 2009; Poling et al., 2012).

A significant fraction of the stimulatory inputs that modulate GnRH secretion is provided by neurons that synthesize glutamate, kisspeptins, and neurokinin B (NKB) as neuronal transmitters (Lomniczi et al., 2013b) (for further details, see sections “Kisspeptins as major regulators of GnRH neurons and puberty onset” and “NKB and Dynorphin as key partners of kisspeptins in the control of GnRH neurons and puberty onset”).

Fig. 1 Schematic representation of the “central drive” hypothesis of puberty. The increase in the pulsatile GnRH release that leads to the onset of puberty is brought about by coordinated changes in trans-synaptic and glial inputs to GnRH neuronal network, consisting of a reduction of inhibitory influences (–) and an increase in stimulatory signals (+). The inhibitory trans-synaptic circuitry is mostly composed of neurons that synthesize RFamide-related peptides (RFRP), γ -aminobutyric acid (GABA), endogenous opioids (EOP), and dynorphin (DYN), whereas the stimulatory counterpart is provided by neurons that produce kisspeptins (KP), neurokinin B (NKB), and glutamate (GLU). Glial cells facilitate GnRH secretion by the release of growth factors and other bioactive molecules. According to this hypothesis, GnRH secretion is restrained by inhibitory influences at early stages of development. At the time of puberty onset, this inhibitory tone is lifted and/or replaced by stimulatory inputs. From Pinilla, L., Aguilar, E., Dieguez, C., Millar, R.P., and Tena-Sempere, M. (2012). Kisspeptins and reproduction: Physiological roles and regulatory mechanisms. *Physiological Reviews* **92**, 1235–1316, with substantial modifications.

Glial cells, such as astrocytes and tanycytes, facilitate GnRH secretion by the release of growth factors and other bioactive molecules, as well as the plastic rearrangement of glial-to-GnRH neuron contacts and adhesiveness (Ojeda et al., 2010).

Kisspeptins as Major Regulators of GnRH Neurons and Puberty Onset

Among the plethora of neuropeptides controlling pubertal GnRH release, kisspeptins hold a prominent place. Indeed, they are currently recognized as one of the most powerful activators, if not the most, of the GnRH/gonadotropin system during the pubertal transition (Pinilla et al., 2012). Kisspeptins are a family of structurally related peptides, encoded by *KISS1/Kiss1* gene, that act through binding and subsequent activation of the G protein-coupled receptor, Gpr54, which is also termed kisspeptin receptor or Kiss1R (Oakley et al., 2009; Pinilla et al., 2012). The pubertal dimension of kisspeptins was unveiled in 2003, when inactivating mutations of *GPR54* were associated with lack of pubertal progression and hypogonadotropic hypogonadism in humans (de Roux et al., 2003; Seminara et al., 2003). These findings were later supported by similar phenotypes of mice with genetic inactivation of *Gpr54* or *Kiss1*, and humans with inactivating mutations of *KISS1* (Pinilla et al., 2012). Those observations paved the way for the analysis of the physiological roles of kisspeptin neurons in the control of GnRH pulsatile secretion and (eventually) the onset of puberty. These studies have documented a sophisticated developmental program responsible for the activation of the Kiss1 neuronal system during the pubertal transition (Pinilla et al., 2012; Tena-Sempere, 2013). Such program involves the following major components: (i) a hypothalamic rise of Kiss1 mRNA/peptide content during the juvenile–pubertal transition, which seems to be sufficient to induce a state of full activation of the GnRH/LH system (Navarro et al., 2004a,b; Plant et al., 2006; Shahab et al., 2005); (ii) an increase in the sensitivity to the excitatory actions of kisspeptins on GnRH/LH release (Castellano et al., 2006a; Han et al., 2005); (iii) an augmentation of Gpr54 signaling efficiency at GnRH neurons, coupled to a state of resistance to desensitization to kisspeptin stimulation (Han et al., 2005; Roa et al., 2008); and (iv) an increase in the number of kisspeptin-positive neurons and their projections to GnRH neurons (Bentsen et al., 2010; Clarkson and Herbison, 2006).

Additional pharmacological and genetic studies have further attested the relevance of proper kisspeptin signaling for the precise timing of puberty in females. Thus, daily injections of a synthetic kisspeptin analog, Kp-10, in prepubertal female mice resulted in precocious puberty onset, as estimated by earlier VO and FE. Furthermore, this pubertal phenotype was associated with a direct stimulation of GnRH neurons (Decourt et al., 2016). In contrast, central infusion of a kisspeptin antagonist, p234, in prepubertal female rats led to delayed VO and reduced uterus and ovarian weights (Pineda et al., 2010); a phenomenon that is seemingly linked to a suppression of GnRH secretion, as subsequently demonstrated in prepubertal and pubertal female rhesus monkeys (Guerriero

et al., 2012). In the same vein, experiments of genetic manipulation showed that the timed ablation of Kiss1-expressing neurons in juvenile female mice prevented the attainment of reproductive competence (Mayer and Boehm, 2011).

Detailed neuroanatomical studies in mammals have identified two major hypothalamic populations of kisspeptin neurons in the ventral forebrain. One of these populations is located in the rostral periventricular area of the 3rd ventricle (RP3V), and the other is found in the arcuate nucleus (ARC; infundibular region in humans) (Garcia-Galiano et al., 2012; Smith et al., 2005a). These two populations seem to be functionally different. While RP3V kisspeptin neurons respond to estrogen with increased production of kisspeptin, the synthesis of kisspeptin is inhibited by estrogen in the ARC (Smith et al., 2005a,b). These and other observations have led to the concept that RP3V kisspeptin neurons are involved in positive feedback and the genesis of the preovulatory LH surge in females, whereas ARC kisspeptin neurons mediate the inhibitory effect of estrogen on GnRH/gonadotropin release and are therefore crucial for the tonic pulsatile secretion of gonadotropins (Pinilla et al., 2012).

The relative contribution of the different kisspeptin neuronal populations to the precise timing of puberty has been partially addressed in recent years. Expression analyses revealed an increase of kisspeptin content in the RP3V of female mice from the infantile to the pubertal period (Clarkson and Herbison, 2006). Furthermore, virogenetic experiments involving the partial knocking down of kisspeptin expression either into the RP3V or ARC of female rats documented a partial delay in the onset of puberty only after targeting RP3V kisspeptin neurons (Hu et al., 2015). Although the latter may suggest a relevant role of RP3V kisspeptin neurons in the timing of female puberty, these findings must be taken with caution due to the moderate kisspeptin suppression obtained with this virogenetic approach in both kisspeptin neuronal populations.

Anyhow, it is worth to note that experimental evidence arguing against an indispensable role of kisspeptin signaling in the onset of puberty has also been presented, as congenital ablation of kisspeptin neurons in female mice appeared to be compatible with the attainment of adult fertility (Mayer and Boehm, 2011). It can be argued, however, that this phenotype could be due to an incomplete neuronal ablation and/or developmental compensation. Indeed, as mentioned above, the same study showed that timed elimination of kisspeptin neurons during the early juvenile period prevented normal pubertal maturation and caused infertility (Mayer and Boehm, 2011).

NKB and Dynorphin as Key Partners of Kisspeptins in the Control of GnRH Neurons and Puberty Onset

The recent identification of NKB and dynorphin (Dyn), as products and putative co-regulators of kisspeptin neurons, has represented an important breakthrough in our understanding of the mechanisms controlling kisspeptin release and, eventually, the awakening of GnRH/gonadotropin system at puberty (Lehman et al., 2010; Navarro et al., 2009). These co-transmitters are only expressed in a percentage of ARC kisspeptin neurons, which can vary depending on the species, the sex and the functional state of the reproductive axis (Hrabovszky et al., 2012; Overgaard et al., 2014). Because this Kisspeptin neuronal population co-express NKB and Dyn, they have been termed KNDy neurons (acronym made using the underlined words).

Compelling evidence suggests that KNDy neurons are important modulators of GnRH pulsatile release, by dictating patterned kisspeptin secretion on GnRH neurons (Navarro, 2012). In particular, the KNDy hypothesis sets the notion that the dynamic release of kisspeptin from the ARC kisspeptin neurons onto GnRH neurons is tightly regulated by the reciprocal stimulatory and inhibitory actions of NKB and Dyn, respectively (Navarro, 2012). This assumption is primarily based on the presence of numerous collateral projections interconnecting ARC KNDy neurons and the proven expression of NKB and Dyn receptors (NK3R and Oprk1, respectively) in these neurons. The physiological relevance of such system is further strengthened by the clinical findings that patients with mutations of the NKB and NK3R gene display a state of hypogonadotropic hypogonadism similar to that shown in patients with genetic inactivation of KISS1 or GPR54 (Topaloglu et al., 2009).

Our current knowledge about the roles of NKB and Dyn signaling in the control of puberty onset is still limited; yet, mounting evidence suggests their contribution in pubertal timing. Thus, central administration of the NKB agonist, senktide, to prepubertal female rats stimulated LH secretion (Navarro et al., 2012). Furthermore, the developmental expression of the NKB gene in the hypothalamus increases before the rise of Kiss1 mRNA levels in female rodents (Gill et al., 2012), which is compatible with a role of NKB in the pubertal activation of kisspeptin/GnRH secretion (Fergani and Navarro, 2017). The latter is further supported by the moderate delay of puberty onset induced by the central blockade of NKB signaling in female rats (Navarro et al., 2012). Interestingly, an independent study later showed that either stimulation of NKB signaling or inhibition of Dyn induces early puberty onset in female rats (Nakahara et al., 2013). These observations have led to the speculation that the inhibitory action of Dyn on kisspeptin release declines when puberty approaches, whereas the stimulatory effect of NKB on kisspeptin secretion gradually augments during this transition. As a result of these sequential modulatory events, the pulsatile kisspeptin/GnRH/LH release would increase, thus leading to the onset of puberty (Uenoyama et al., 2014).

Finally, it is important to note that congenital NK3R null female mice seem to display normal puberty onset (Yang et al., 2012); yet, these animals do present various reproductive defects, including abnormal estrous cycles, reduced number of corpora lutea, decreased uterine weights, and subfertility (Yang et al., 2012).

Metabolic Influences Regulating the Timing of Female Puberty

The scientific basis for the connection between the magnitude of energy (fat) stores and the timing of puberty was formulated for the first time by Frisch and Revelle in 1970. Their “critical fat mass hypothesis” proposed the need to reach

a certain threshold of body fat mass for the attainment of reproductive capacity (Frisch and Revelle, 1970). This assumption is especially evident in females, in which the acquisition of reproductive capacity involves the potential metabolic drainage of pregnancy and lactation and, therefore requires reaching a minimal level of energy stores. Furthermore, the timing of puberty in females seems to be extremely sensitive to conditions of energy insufficiency (i.e., undernutrition) and energy excess (i.e., overnutrition), as evidenced by different experimental and epidemiological studies (Castellano and Tena-Sempere, 2016).

Leptin as an Essential Gatekeeper of Puberty Onset

The formulation of the critical fat mass hypothesis, and its supporting evidence, fuelled the search of the potential endogenous mediators responsible for transmitting the metabolic information to the brain reproductive centers (mainly, the hypothalamus) that control the onset of puberty. In this context, the identification of the adipose hormone, leptin, represented a significant breakthrough (Vazquez et al., 2015). Indeed, leptin is an ideal candidate for connecting metabolism and reproduction, due to its ability for conveying information regarding the magnitude of fat stores to the hypothalamus, where it acts as an anorexigenic and thermogenic factor to adjust energy requirements, fat reserves, and food intake (Casaneuva and Dieguez, 1999).

The pubertal dimension of leptin is clearly illustrated by the alterations in the timing of puberty associated with conditions of leptin deficiency (e.g., inactivating mutations affecting leptin signaling and malnutrition) and situations of leptin excess (e.g., genetic models of leptin overexpression and early overfeeding), which have been linked to delayed and advanced puberty, respectively (Castellano and Tena-Sempere, 2016; Manfredi-Lozano et al., 2017).

Despite some initial controversy, there is now a broad consensus that leptin plays a major permissive role in the metabolic gating of puberty; an assumption that is based on a large body of evidence. For instance, chronic leptin administration has shown to prevent the delay in the onset of puberty induced by severe undernutrition in female rodents (Cheung et al., 1997, 2001). In the same vein, it has been reported that the maintenance of adequate levels of leptin in conditions of energy insufficiency prevents pubertal delay in female prepubertal rats (Gruaz et al., 1998); a phenomenon that has also been documented in humans, where subcutaneous injections of leptin facilitate pubertal development in obese children congenitally deficient in leptin (Farooqi et al., 2002). As a whole, the above evidence suggests that leptin, rather than a trigger, enables puberty to proceed when its circulating levels achieve a certain threshold.

Interplay of Leptin and Kisspeptins in the Control of Puberty: Direct, Indirect or Independent Actions

How the permissive actions of leptin are transmitted to the GnRH neuronal network during the pubertal transition is still an open question. Studies in rodents and primates suggest that such actions are carried out in an indirect manner, as the expression levels of leptin receptor (LepR) in GnRH neurons seems to be very low or negligible (Finn et al., 1998; Hakansson et al., 1998). Furthermore, when LepR is detected, as it has been shown in female mice, its selective elimination in GnRH neurons does not cause any alteration in the timing of puberty (Quennell et al., 2009).

The above observations clearly suggest the potential involvement of central mediators for transmitting the pubertal actions of leptin onto GnRH neurons. Among them, kisspeptin neurons have received special attention in recent years (see Fig. 2). The first studies addressing the potential role of kisspeptins as putative mediators of leptin actions onto GnRH neurons supported a direct connection between leptin and kisspeptin. This assumption was based on the following pieces of evidence: (i) conditions of leptin deficiency (i.e., undernutrition) suppresses hypothalamic *Kiss1* expression in rodents and sheep (Castellano and Tena-Sempere, 2016; Manfredi-Lozano et al., 2017), (ii) leptin administration activates kisspeptin neurons or increase *Kiss1* expression in vivo (Backholer et al., 2010; Castellano et al., 2006b; Qiu et al., 2011; Smith et al., 2006), and in vitro (Luque et al., 2007; Morelli et al., 2008); and (iii) LepR mRNA is detected in a subset of ARC kisspeptin neurons in mice and ewes (Quennell et al., 2011; Smith et al., 2006).

Despite the above data suggested a direct mode of action of leptin on kisspeptin neurons, subsequent findings have (partially) questioned this assumption. Thus, studies in a *Kiss1-Cre* mouse model that allows the identification of kisspeptin neurons evidenced that only a small fraction of ARC kisspeptin neurons responds to leptin stimulation (Cravo et al., 2011). Moreover, the congenital ablation of LepR from kisspeptin neurons did not prevent the onset of puberty in female mice (Cravo et al., 2011). Additional studies have not been able to detect functional LepRs in kisspeptin neurons before puberty (Cravo et al., 2013; Qiu et al., 2015), while suggested that LepR might become expressed in this neuronal population in adulthood (Cravo et al., 2013; Qiu et al., 2011, 2015). One of those studies also demonstrated the expression of LepR in populations of ARC and RP3V neurons, of unknown nature, in close vicinity of kisspeptin neurons. Moreover, a relevant population of neurons expressing LepR has also been described in the hypothalamic premammillary nucleus (PMV). The physiological relevance of such population is demonstrated by the rescue of puberty onset induced by the selective re-expression of LepR in the PMV of female db/db mice, devoid of LepR (Donato et al., 2011). This study also showed that PMV neurons expressing LepR innervate kisspeptin neurons, suggesting their potential interplay with kisspeptin signaling in the metabolic control of puberty. Overall, these observations are compatible with an indirect (or even independent) mode of action of leptin on kisspeptin neurons in the control of female puberty.

Fig. 2 Tentative scheme showing the direct (1), indirect (2) and independent (3) mode of action of leptin on kisspeptin pathways controlling GnRH neurons. While initial evidence supported a direct connection between leptin and kisspeptin (1), further studies suggest the potential involvement of an unknown population of ARC and R3PV neurons located in close vicinity of kisspeptin neurons (2) and the novel role of a neuronal population expressing LepR in the hypothalamic PMV (3). Of note, the major actions of leptin on PMV nucleus, which were initially considered as kisspeptin-independent, do not rule out the existence of some interaction with kisspeptin circuits (represented as a *dotted line* projection).

Novel Signals and Mechanisms for the Control of Female Puberty

The complex and sophisticated nature of puberty, and its sensitivity to different regulators, strongly suggest the involvement of diverse but complementary regulatory mechanisms, enabling such a degree of precise control. Emerging evidence is mounting that such intricate control likely involves epigenetic regulatory mechanisms. Those mechanisms mainly include: (i) DNA methylation, which consists of the incorporation of methyl groups to CpG islands in the DNA and is often associated with gene repression (Paulsen et al., 2008); (ii) histone modifications (e.g., acetylation, methylation, and phosphorylation), whose effects on gene expression, in terms of activation or repression, depends on the histone and residue subjected to modification (Sims et al., 2008); (iii) and miRNAs, which are small, noncoding RNAs that can modulate (mainly repress) gene/protein expression, predominantly by interaction with seed regions at the 3' untranslated region (3'-UTR) of target genes (Sayed and Abdellatif, 2011).

Roles of the Polycomb Group and Zinc Finger Proteins

Recent evidence suggests the involvement of an epigenetic mechanism of transcriptional repression in the central control of female puberty (Lomniczi et al., 2013a). This mechanism is driven by two members of the so-called Polycomb group, namely Eed and Cbx7. Lomniczi and colleagues showed that the hypothalamic expression of these two genes decreases during the juvenile–pubertal transition owing to the enhanced methylation pattern of their promoters (Lomniczi et al., 2013a). In line with this finding, the pharmacological inhibition of DNA methylation in juvenile female rats, a manipulation that may prevent the pubertal decrease of *Eed* and *Cbx7* expression, delayed the onset of puberty (Lomniczi et al., 2013a). This epigenetic repressive mechanism was shown to modulate the hypothalamic expression of *Kiss1* (Lomniczi et al., 2013a). Thus, the increase of *Kiss1* mRNA levels preceding the onset of puberty was accompanied by the removal of EED from *Kiss1* promoter and the enrichment of histone modifications linked to gene activation (Lomniczi et al., 2013a). In contrast, the prevention of the loss of EED from the *Kiss1* promoter disrupted GnRH pulsatile release and delayed the timing of puberty (Lomniczi et al., 2013a).

Further studies have reported a similar epigenetic mechanism of transcriptional repression in female primates and rats. This mechanism is conducted by GATAD1 and ZNF573, two members of the family of transcriptional repressors Zinc Finger (ZNF) genes (Lomniczi et al., 2015). The hypothalamic expression of these two genes has been shown to decrease in peripubertal female monkeys (Lomniczi et al., 2015). The physiological relevance of this phenomenon was confirmed by further functional analyses in female rats. Thus, *GATAD1* or *ZNF573* overexpression in the ARC of juvenile female rats delayed the onset of puberty; a phenomenon that was associated with changes in the epigenetic landscape of the hypothalamus (Lomniczi et al., 2015). Importantly, GATAD1 evoked the transcriptional repression of *KISS1* and *TAC3* genes through an epigenetic mechanism that implies the eviction of the activating histone mark H3K4me2 from *KISS1* and *TAC3* promoters via the recruitment of the histone demethylase KDM1A (Lomniczi et al., 2015).

An additional member of the superfamily of ZNF genes that may also contribute to the transcriptional silencing of female puberty is Makorin 3 (MKRN3). *MKRN3* is an intron-less, maternally imprinted gene that encodes a protein with a conserved RING finger domain and several ZNF motifs with predicted ubiquitin-protein isopeptide ligase E3 activity (Jong et al., 1999). The potential repressive role of MKRN3 in the control of puberty has been suggested by the presence of inactivating mutations of MKRN3 in girls and boys with precocious puberty (Abreu et al., 2013); a phenomenon that has been documented by several independent studies in different human populations (Abreu et al., 2015). In line with these findings, a decline in the hypothalamic expression of *Mkfn3* has been detected in both male and female mice during the prepubertal development (Abreu et al., 2013). Furthermore, recent studies have demonstrated a decrease in the serum levels of MKRN3 before the onset of puberty in healthy girls and boys (Abreu et al., 2015). Overall, these data support the potential repressive role of MKRN3 in the control of puberty; yet, further studies are required to demonstrate the precise mechanism of action of MKRN3 in such context.

Roles of miRNA Regulatory Pathways

The first indirect evidence for a role of miRNAs in the timing of puberty came from genome-wide association (GWAS) studies that revealed an association of the age at menarche with variability at 6q21 chromosome, in or near the *LIN28B* gene (Elks et al., 2010). *LIN28B* encodes a cytoplasmic protein that blocks the processing of mature miRNAs of the let-7 family (Viswanathan et al., 2008). Interestingly, reciprocal changes in the hypothalamic expression of *Lin28b* and let-7 (as well as related miRNAs, for example, miR-132, miR-145) have been documented in female rats during postnatal development (Sangiao-Alvarellos et al., 2013). Thus, while *lin28b* mRNA levels decrease along the prepubertal period, the mRNA expression of let7 increases during this transition (Sangiao-Alvarellos et al., 2013). Moreover, altered ratios of *Lin28b*/let7 levels have also been documented in different rodent models of perturbed puberty (Sangiao-Alvarellos et al., 2013). As a whole, the above findings strongly suggest the potential role of the *Lin28b*/let7 miRNA system in pubertal modulation; yet, functional data showing the impact of such alterations in the onset of puberty are still missing.

Interestingly, a very recent study has provided a more direct evidence for the pubertal role of miRNA regulatory pathways in the control of puberty. In particular, Messina and coworkers have demonstrated a switch in the miRNA expression profiles of GnRH neurons during the infantile period that precedes to, and seems mandatory for, the onset of puberty in rodents (Messina et al., 2016). This switch involves significant alterations in the expression of members of the miR-155 and miR-200 families that seem to be mandatory for appropriate activation of GnRH neurosecretion during the pubertal transition (Messina et al., 2016). In line with this finding, genetic ablation of *Dicer*, the enzyme responsible for the generation of mature miRNAs, in GnRH neurons prevented normal pubertal maturation in both male and female mice and resulted in central hypogonadism and infertility (Messina et al., 2016).

Glossary

α -MSH A neuropeptide hormone encoded by the *POMC* gene that suppresses appetite and stimulates GnRH release.

Anterior pituitary Glandular organ that secretes several hormones, including FSH and LH, to regulate several physiological processes, such as reproduction, stress, growth, and lactation.

Arcuate nucleus Hypothalamic region adjacent to the third ventricle that contains several neurons responsible for integrating nutritional and metabolic information.

Epigenetics The study of changes in phenotype caused by modification of gene expression rather than alteration of the genetic code itself.

Estradiol Steroid hormone produced chiefly by the ovarian follicle and the primary female sex hormone.

Follicle-stimulating hormone (FSH) Hormone produced by the pituitary gonadotropes responsible for controlling the initiation of follicular growth.

Gonadotropin-releasing hormone (GnRH) Hypothalamic neuropeptide responsible for the release of FSH and LH from the anterior pituitary.

Gonadotrope Specialized cell in the anterior pituitary that secretes LH and/or FSH.

Hypothalamus Portion in the ventral region of the brain that links the nervous system to the endocrine system to control reproduction and other biological processes.

Hypothalamic-hypophyseal portal system A system of blood vessels in the brain that connects the hypothalamus with the anterior pituitary. Its main function is the transport and delivery of hormones to the anterior pituitary (adenohypophysis).

Juvenile period Usually defined as the period beginning when the offspring no longer needs nourishment from the dam but before sexual maturation.

Kisspeptin Peptide encoded by the *KISS1* gene and a potent stimulator of GnRH neurons.

KNDy neurons Neurons located in the arcuate nucleus that co-express kisspeptin, neurokinin B, and dynorphin.

Leptin Hormone produced by adipose cells that acts at the brain level to regulate energy metabolism and reproduction.

Luteinizing hormone (LH) Hormone produced by the pituitary gonadotropes responsible for controlling follicular development and ovulation.

Median eminence Part of the hypothalamus from which regulatory hormones are released via the hypophyseal portal system; connects the neural and peripheral endocrine systems.

Menarche Beginning of menstrual cycles in humans and some nonhuman primates.

Neuropeptide Y Neuropeptide produced in several brain regions, including the hypothalamus, that stimulates food intake and suppresses GnRH release.

Ovulation Release of an oocyte (egg) from the ovaries.

Proopiomelanocortin (POMC) Precursor polypeptide that is cleaved in different peptide hormones that control energy balance and reproduction among other processes.

Puberty Process of biological and physical changes through which an individual matures to acquire reproductive competence.

Introduction

Puberty in females is a complex biological process involving both physical and behavioral changes, including those associated with the activation of specific neuronal pathways within the hypothalamus. The latter events lead to the initiation of high-frequency episodic release of gonadotropin-releasing hormone (GnRH) from GnRH neurons, a corresponding pattern of luteinizing hormone (LH) secretion from anterior pituitary gonadotropes, functional maturation of ovarian follicles, and subsequent establishment of ovulatory cycles (1). Pubertal development is controlled largely by genetic and environmental factors, among which nutrition plays a prominent role. The timing of pubertal onset has important relevance for both human health and livestock production. Both epidemiological data and animal studies have shown that increased postnatal nutrient intake, particularly during the juvenile period, has major impacts on the programming of puberty in females (2). For example, precocious puberty is associated with increased risk of unwanted pregnancies in all female mammals, and in girls a heightened risk of polycystic ovary syndrome,

reproductive cancers, and psychological distress (3). In contrast, delayed puberty negatively impacts reproductive performance and lifetime productivity in livestock species. The objectives of this article are to present an overview of the events within the brain and pituitary that control puberty in female mammals and to summarize recent research findings regarding the nutritional and metabolic control of the pubertal process.

Developmental Processes Underlying the Path to Fertility

Female puberty, which culminates ultimately in the functional potential to become pregnant, occurs as the result of a series of developmental events that begin as early as the prenatal period and conclude under normal circumstances after the juvenile period. At least three definitions of female puberty can be considered, all of which have relevance depending on one's focus: (1) *Neuroendocrine puberty*: a state of development reflecting maturity of hypothalamic centers responsible for both tonic (basal) and surge release of gonadotropins (LH and follicle-stimulating hormone (FSH)) in response to the negative and positive feedback of the most important biologically-functional estrogen, estradiol-17 β ; (2) *First estrus*: the exhibition of female sexual receptivity in nonhuman species in association with the development of a mature, estrogen-active ovarian follicle; (3) *First ovulation*: onset of ovarian cyclicity and menstrual cycles (girls and some nonhuman primates), thus the ability to become pregnant. Although the ability to become pregnant is the most frequently used definition of puberty, both first estrus and first ovulation are the most common markers used for assessing this potential in female (nonhuman) domestic species. However, both are subject to errors of interpretation. For example, the phenomenon of "nonpubertal estrus" is a documented phenomenon in some females (e.g., bovine females) and first ovulation is not always associated with estrus or fertility. Numerous genetic and environmental factors can influence all the foregoing events but, as noted earlier and discussed in detail later, both pre- and postnatal nutrition play a remarkable role in timing their onset.

Hypothalamic–Pituitary Axis

The endogenous secretion of gonadotropins (FSH and LH) during early (pre- and postnatal) development exhibits distinct patterns characteristic of the species. In general, these patterns tend to favor relatively high circulating concentrations of FSH during early development, followed by marked declines in advance of the juvenile period. Diminution of the early postnatal FSH rise in the laboratory rat begins at about 3 weeks of age, whereas in sheep, circulating FSH tends to remain elevated throughout the developmental period leading up to puberty. A mid-gestational rise in both LH and FSH is observed in human and nonhuman primate fetuses that declines at birth, followed by a postnatal rise and a second decline during the juvenile period.

During the postnatal period, the synthesis and secretion of gonadotropins appears to be largely gonadal steroid-independent. However, as development proceeds to the juvenile period, a gonad-dependent suppression of LH develops due to an increase in sensitivity to the negative feedback effects of estradiol. Although both FSH and LH are ultimately controlled by GnRH from the hypothalamus, secretion patterns of these two gonadotropins are often quite different. This differential pattern of release is controlled by contrasting responses of gonadotropes that secrete primarily either FSH or LH, by differences in estradiol ovarian steroid feedback effects on FSH- and LH-secreting gonadotropes, and by the release of regulatory peptides (e.g., activin and inhibin) from maturing ovarian follicles. The biological activity of FSH can also vary dramatically because of the production of heterogeneous forms of FSH diverging in their degree of glycosylation. However, in general, a limitation in availability of FSH is not a primary factor regulating the timing of puberty in the female, but rather the lack of a high-frequency pattern of pulsatile LH release. In many species, a decrease in estradiol negative feedback sensitivity during the late juvenile period times the onset of puberty. This modulatory effect was first described in the rat and is the basis for the transition to a high-frequency pattern of GnRH/LH release, a neuroendocrine event critical to the onset of puberty in the female. However, the escape from enhanced negative feedback sensitivity to estradiol apparently is not a critical event for pubertal progression in humans and nonhuman primates. Thus, a juvenile hiatus in both LH and FSH secretion occurs in these species that appears to be gonad independent, at least in the female. After the juvenile hiatus, the increase in circulating LH, and in some species FSH, results in heightened stimulation of ovarian follicles, an increase in circulating concentrations of estradiol, and initiation of an LH surge (Fig. 1). The latter occurs through a separate positive feedback effect of estradiol at the hypothalamic level which induces a prolonged surge of GnRH. In most species, estradiol positive feedback mechanisms, and thus the ability of estradiol to induce a surge release of GnRH/LH, is functional well before puberty.

Hierarchical Network Regulating Secretion of GnRH

For many years, hypothalamic secretion of GnRH has been defined as the master controller of reproduction. The inherent propensity for the GnRH neuronal network to produce a pulsatile pattern of GnRH release, which depends upon synchronous firing of GnRH neurons, has been referred to as the "GnRH pulse generator." However, insight into the exact mechanisms through which the pulse generator is regulated has until recently been lacking. In the mid-1990s, the discovery and characterization of the peptide, kisspeptin dramatically changed our understanding of how GnRH neuronal activity is synchronized. Kisspeptin, which is part of the RF-amide related peptide (RFRP) superfamily, was originally identified simply as a regulator of tumor metastasis and was called metastin. It was soon discovered that the gene for this peptide, named *KISS1* after the location (Hershey, PA) where it was first identified, as well as its G protein-coupled receptor (GPR54), were expressed in a variety of tissues, including the hypothalamus.

Fig. 1 Developmental changes and nutritional facilitation of puberty. (A) Representative scheme of major neuronal groups involved with the nutritional control of puberty that are located in the basal portion of the brain (*A-inset*) within the preoptic area and the hypothalamic arcuate nucleus (ARC). The population of kisspeptin (Kiss) neurons located in the ARC is also known as KNDy neurons. Kisspeptin, POMC, NPY/AgRP neurons communicate with gonadotropin-releasing hormone (GnRH) neurons (and with each other) by delivery of their respective neuropeptides through axonal projections directed to neuronal (GnRH) cell bodies. Kisspeptin neurons are important conveyors of the estradiol effects on GnRH neurons while POMC and NPY/AgRP neurons are the major ARC neurons that communicate metabolic status to GnRH neurons. GnRH neurons send projections to the hypophyseal portal circulation (represented in pink), allowing the access of this neurohormone to the anterior pituitary, where it stimulates the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). (B–D) Representative graphs depicting the pattern of GnRH and LH secretion in the prepubertal (B), peripubertal (C), and pubertal phases (D) of development in the female. Concentrations of LH refer to those in peripheral plasma, while GnRH is measured directly in hypophyseal portal blood or indirectly in third ventricle cerebrospinal fluid. The pulsatile pattern of GnRH and LH release occurs sporadically during the prepubertal period (B), increases in frequency as puberty approaches (C), and reaches a high frequency pattern (D, hours 0–4) before the first ovulation. The enhancement of GnRH/LH pulse frequency in many species is related to the reduction in the sensitivity to the negative feedback of estradiol. Ovulation occurs when a threshold level of estradiol is released that initiates a positive feedback effect at the hypothalamus that induces the release of GnRH and LH in a surge fashion (D, hours 4–14). (E) Schematic representation of events that culminate with the nutritional facilitation of puberty. Full *green arrows* represent stimulatory (thickness relates to the intensity of the stimulus) while *black dashed lines* represent inhibitory inputs. A favorable energetic status increases stimulatory and suppresses inhibitory pathways, permitting, or even accelerating, activation of the hypothalamic–pituitary–gonadal (HPG) axis, culminating with the first ovulation.

The peptide, now renamed kisspeptin, and mutations in the GPR54 receptor (now termed KISS1R), were found subsequently to play a major role in a condition in humans termed idiopathic hypogonadotropic hypogonadism. Through additional study with KISS1R knockout mice, it became apparent that kisspeptin was the natural ligand for KISS1R. This led to studies which localized both KISS1 and KISS1R within the hypothalamus and observations that KISS1R colocalized with GnRH neurons. Ultimately, it became obvious that kisspeptin-containing neurons within the hypothalamus were responsible for regulating the release of GnRH. A plethora of subsequent studies has now confirmed that the kisspeptin-KISS1R-connection in GnRH neurons is a critical element in the normal regulation of GnRH secretion (Fig. 1). Gene mutations resulting in a breakdown of this signaling pathway result in the failure to attain puberty and thus persistent infertility.

Recently, a further delineation of the chemical architecture of kisspeptin neurons has revealed additional variants that may explain the ontogeny of the GnRH pulse generator itself. Kisspeptin cells localized to the arcuate nucleus (ARC) of the hypothalamus are now referred to as KNDy neurons. They have been given this name because they co-express two other neuronal peptides, neurokinin B (NKB) and dynorphin. KNDy neurons express receptors for their own ligands, namely NKB and dynorphin, but do not contain kisspeptin receptors. These cells function as an interconnected network, secreting kisspeptin in response to their own release of NKB. Activation of the NKB receptor results in kisspeptin release at two locations: GnRH cell bodies and their terminals in the median eminence of the hypothalamus. This cascade initiates the transport of GnRH to the anterior pituitary via hypophyseal portal vessels and causes release of gonadotropins. It is believed that the activation of KNDy neurons results in the release of dynorphin which then terminates KNDy neuron activity. The repeating nature of this locally-controlled cycle provides one of the first plausible accounts of cellular activity that could represent the physical source of the GnRH pulse generator. It has also become obvious that the hypothalamus of at least some species contains two populations of kisspeptin neurons. Those located in the ARC are KNDy neurons because of their chemical constituents. A second population of kisspeptin neurons can be observed in the rostral or frontal part of the hypothalamus that do not contain NKB or dynorphin. However, both sets of neurons contain estrogen receptor alpha ($ER\alpha$). Estradiol suppresses *KISS1* expression in the ARC but has a positive feedback effect on kisspeptin neurons located in the rostral hypothalamus. Deletion of $ER\alpha$ in all kisspeptin-expressing neurons in mice advances the onset of puberty, supporting the contention that $ER\alpha$ has the inherent ability to restrain GnRH/LH secretion, ovarian function, and pubertal onset. The interrelationship between $ER\alpha$ and kisspeptin neurons provides a potential basis through which changes in negative feedback sensitivity to estradiol could regulate the timing of puberty, as described earlier in this article.

Energy Nutrition and the Central Control of Puberty

Reaching a threshold of body size and amount of stored energy before activation of reproductive processes that lead to pregnancy is an effective evolutionary strategy for female mammals to use for successful reproduction. The physiological mechanisms controlling energy metabolism, which include intake, expenditure and storage, are in part intermingled with the components that limit or time pubertal development. Not surprisingly, nutritional influences on puberty appear to be more robust in females, likely due to the energy-consuming activities of gestation and lactation, and in some species the final phases of growth. In mammals, it is broadly accepted that an adequate adipose reserve is necessary for puberty, an event often delayed under conditions of undernourishment and advanced in response to overnutrition.

Nutritional and Metabolic Signals that Time the Onset of Puberty

The central nervous system (CNS) perceives information regarding the energetic status of an individual by means of circulating nutritional and metabolic signals. Several of those metabolic signals influence the release of GnRH and LH, including their prepubertal rise. The hormones insulin, insulin-like growth factor-1 (IGF1), leptin, and ghrelin are circulating metabolically-controlled hormones that have been demonstrated to have the greatest influence on puberty. Both insulin, produced in the pancreas, and IGF1, a mediator of growth hormone (GH) action and produced in the liver, signal favorable energetic scenarios. Conversely, ghrelin, produced mainly in the stomach, is released under circumstances of fasting or low energy status. As an inhibitory signal to GnRH neurons, ghrelin appears to be dispensable for normal reproductive function but may play a role in postponing puberty onset. The structurally-homologous hormones insulin and IGF1 have stimulatory roles regarding GnRH release and facilitate growth and developmental events that support the pubertal process.

The adipokine leptin, which is synthesized primarily by adipocytes and whose synthesis and secretion increase in concert with increasing adiposity, plays a permissive role in the establishment of puberty. The complete knockout of leptin or its receptor results in infertility. Replacement of leptin in leptin-deficient females restores fertility. In this context, it has long been known that a critical amount of fat is necessary for adequate fertility. In female mammals, drastic reductions in adipose reserve are associated with adverse reproductive effects that persist until adiposity is restored to normal levels. Because reproduction is suspended well in advance of starvation, protective mechanisms that communicate negative energy balance to the central reproductive axis must be operable. The idea that a permissive signal produced by the adipose tissue informs the brain of energy status was first proposed in the 1950s and led to the characterization of the obese (*ob/ob*) mouse and the discovery of the leptin gene in 1994. Since its discovery as a peptide hormone synthesized primarily by adipose cells, and the finding that recombinant leptin not only normalized the obese and diabetic state in *ob/ob* mice but also restored fertility, leptin's role as a key player communicating energy reserves to the hypothalamus has become well-accepted. A concerted effort to characterize the physiological role of leptin and the mechanisms that govern its actions followed. In ruminant females, the stimulatory effects of leptin on secretion of LH are confined predominantly to periods of nutritional stress and occur through direct actions at both the hypothalamic and pituitary levels. Importantly, leptin appears to influence the secretion of GnRH at the hypothalamic level by modulating the sensitivity of the neuroendocrine system to steroid feedback as well as via steroid-independent mechanisms. The majority of GnRH neurons do not express the leptin receptor or intracellular sex steroid receptors, and leptin and other hormonal/metabolic factors regulate GnRH release via a complex neuronal network that has only recently begun to be characterized (Fig. 1).

Morphological Changes in Neuronal Pathways Controlling Puberty

Among the various functions of leptin is the ability to modulate axonal growth, neurogenesis and synaptogenesis. Leptin signaling during early life influences adult morphology and function of hypothalamic circuitries related to metabolism. Insulin and IGF1 also elicit neuronal remodeling, and IGF1 has been demonstrated to alter the morphology of GnRH neurons. Therefore, nutrition can influence reproductive function by promoting morphological alterations that result in remodeling of neurocircuitries capable of balancing inhibitory and stimulatory inputs to GnRH neurons. Interestingly, such modifications appear to be long-lasting. For example, neonatal nutritional manipulation in rodents alters the number or density of kisspeptin fibers in close apposition to GnRH neurons, and thus are increased by overnutrition and decreased by undernutrition. This is reinforced by our findings in the female bovine showing that a high nutritional plane during the juvenile period results in an acute increase in circulating concentrations of leptin, which promotes altered expression of several genes related to neuronal remodeling in the ARC, a reduction of direct NPY innervation of GnRH neurons, reductions in NPY tone as measured in third ventricle cerebrospinal fluid, and increased alpha melanocyte-stimulating hormone (α -MSH) innervation of kisspeptin neurons. Thus, nutritional plane during early life can create favorable metabolic conditions characterized primarily by increased circulating concentrations of leptin, lower hypothalamic NPY release, heightened pulsatile release of LH, and hastened onset of puberty (Fig. 1).

Epigenetic Modulation of Puberty

Recent advances in the emerging field of epigenetics have revealed that the fetal environment during mid- to late gestation may play a pivotal role in determining both postnatal and adult phenotype, including mechanisms involved in the restraint or acceleration of pubertal development. In this context, the neuroendocrine axis is responsible for integrating the operational control of a variety of nutritional and reproductive processes, including feed intake, satiety, metabolic homeostasis, reproductive cyclicity, and pregnancy. Mounting evidence has shown that nutritional imbalances during perinatal development can permanently alter the organization of this system, resulting in lifelong alterations of reproductive function in female offspring. Of significant importance are observations that both *excessive* and *deficient* maternal nutrition during gestation can cause phenotypically indistinguishable disorders of metabolism in the offspring. Restraining or stimulating pubertal development by altering the functions of neuronal populations related to the control of GnRH release is one potential mechanism through which metabolic state can create epigenetic effects. For example, it is plausible that KNDy neurons are targets for epigenetic modifications which would involve gene groups controlling *KISS1* transcription, *KISS1* or *Tac3* which encodes NKB. Epigenetic modifications in other ARC neuronal populations, such as those affecting the *POMC* gene, may also occur as a result of altered nutritional conditions that have been linked with advanced or delayed puberty. In female cattle, altered DNA methylation within the ARC has been shown to target many genes, including those encoding the growth hormone receptor (*GHR*) and a chromatin-associated protein (*HMG2*). Both genes have been implicated in the control of puberty onset in this species.

Genetic and Environmental Perturbations of Puberty

Precocious Puberty

Precocious puberty in girls is defined by the development of secondary sexual characteristics before the age of 8 years and is one of the most common conditions encountered in pediatric endocrinology practice. Central precocious puberty (CPP) is characterized by premature activation of the hypothalamic-pituitary-ovarian axis and increased secretion of GnRH/LH, accounting for approximately 90% of precocious puberty cases. In girls, precocious puberty is associated with greater risks of breast cancer, endometrial cancer, obesity, and cardiovascular disease. While most CPP cases are considered idiopathic, compelling evidence from population studies indicates that genetic factors influence timing of puberty in girls.

During the past few decades, several of the genetic determinants regulating pubertal development in females have been identified. In addition to mutations in the *KISS1* gene and its receptor *KISS1R* as discussed earlier in this chapter, loss-of-function mutations in the maternally-imprinted gene *MKRN3*, the gene encoding makorin RING-finger protein 3, has also been associated with CPP in humans. Notably, expression of *Mkrn3* mRNA in the ARC declines drastically immediately before puberty in female mice, providing further support for *MKRN3* as an important inhibitory factor controlling puberty in females. While these studies clearly implicate genetic factors in the control of precocious puberty, the rapid increase in frequency of accelerated timing of puberty in the last two decades point to an environmental etiology. In this regard, the obesity epidemic affecting both children and adults worldwide has received special attention.

Many studies have investigated the relationship between obesity, measured primarily by body mass index, and timing of puberty in girls. These studies have demonstrated that increased adiposity during childhood is associated with early reproductive maturation in girls. Obesity is approximately 1.5-fold more prevalent in girls who reach puberty at an earlier-than-average age and overweight girls are twice more likely to achieve puberty than average-weight girls of the same age. Similarly, animal studies have also identified a link between increased adiposity during juvenile development and precocious puberty in females. In female rats, postnatal overfeeding resulted in increased circulating concentrations of leptin and earlier age of vaginal opening, an external sign of puberty. Moreover, feeding female rhesus monkeys a high-calorie diet during juvenile development results in increased circulating concentrations of leptin and IGF1, and a greater incidence of precocious menarche. In cattle, a larger proportion of females fed to gain body weight at high rates during the juvenile period also exhibit precocious puberty, which is associated with an attenuation of

Fig. 2 Genetic and environmental perturbations of puberty. Genetic alterations (e.g., loss-of-function mutations) and environmental insults (e.g., malnutrition and exposure to endocrine disrupting chemicals (EDCs)) can disrupt the normal pubertal development in females resulting in perturbations of puberty, such as precocious or delayed puberty. Importantly, environmental insults occurring not only during postnatal life but also during in utero development can disrupt the progression of puberty in female mammals.

estradiol inhibitory effects on secretion of LH. Although there are several differences in the endocrine events that precede puberty among the foregoing species, the causal link between juvenile weight gain and adiposity and greater incidence of precocious puberty appears to be conserved in females across species, including women, rodents, nonhuman primates, and livestock species such as ruminants.

More recent evidence from epidemiological and animal studies indicates that not only does metabolic status during peripubertal development influence the timing of puberty in females but also metabolic changes occurring during prenatal/early postnatal life. For example, girls considered to be small for gestational age (SGA) at birth due to maternal malnutrition exhibit a greater incidence of precocious puberty. Daughters of obese mothers also present with advanced reproductive maturation; thus, the relationship between maternal nutrition and timing of puberty in female offspring is not a simple linear association. Instead, it appears to follow a U-shaped curve. Similar findings have also been observed in the laboratory rat, in which both maternal caloric restriction and maternal high fat nutrition result in early pubertal onset in the female offspring. Likewise, both maternal under- and overnutrition have been shown to induce juvenile obese phenotype and precocious puberty in female pigs. While a comprehensive review of the factors associated with the development of precocious puberty is beyond the scope of this chapter, it is noteworthy that a clear cause-and-effect relationship between environmental exposure to endocrine disrupting chemicals (EDCs) and perturbations of puberty has been observed. Taken together, these observations emphasize the idea that puberty is the endpoint of a maturational continuum that likely begins before birth and is modulated throughout development by genetic and environmental factors (Fig. 2).

Delayed Puberty

Delayed puberty in girls is defined as the absence of breast development at an age that is 2–2.5 standard deviations later than the population average (traditionally, 13 years in girls). Late pubertal onset can have negative effects on psychosocial well-being and can impact the normal pubertal growth spurt, thus affecting multiple organ systems. The cause of delayed puberty is unknown but, similar to precocious puberty, it has a strong genetic basis. It has been estimated that approximately 50%–75% of patients with constitutional delay of growth and puberty (CDGP) have a family history of delayed puberty. However, the specific genes involved in the development of CDGP remain largely unknown.

Decreased body fat, which is often associated with low circulating concentrations of leptin, is also a major cause of pubertal delay in females (Fig. 2). Studies examining pubertal onset across multiple populations have shown a negative correlation between socioeconomic status and the age of menarche in girls, suggesting that puberty occurs later in undernourished individuals. Excessive physical activity during childhood and adolescence has also been shown to negatively affect growth and pubertal development in girls. Sports that emphasize strict weight control and high energy output, such as gymnastics and dancing, are of particular concern for pubertal disorders. For example, the hard training schedule associated with low food intake typically observed in young female ballet dancers is often related to excessive thinness and a marked delay in pubertal maturation. Other conditions that result

in reduced energy reserves and low circulating levels of metabolic hormones during juvenile development, such as anorexia nervosa and inflammatory bowel disease, have also been shown to delay the establishment of menstrual cycles in girls.

A number of animal studies support the notion that undernutrition during juvenile life delays the onset of puberty. In rats, postnatal undernutrition associated with large litter size resulted in a persistent reduction in body weight, lower ovarian and uterine weights, and delayed vaginal opening; changes that were paralleled by a reduction in circulating concentrations of leptin and *Kiss1* mRNA expression in the hypothalamus. Similarly, restricted feed intake during juvenile development reduced the pulsatile secretion of LH during the peripubertal period and delayed first ovulation in female sheep. In female pigs, long-term moderate feed restriction during early postnatal life results in over a 3-week delay in the onset of puberty. Collectively, these studies emphasize the fact that a minimal amount of energy reserves and consequently circulating leptin are necessary for the normal progression of puberty in female mammals.

Glossary

- Adrenarche** Appearance of pubic and axillary hair resulting from secretion of androgens from the adrenal gland.
- Thelarche** Beginning of breast development.
- Menarche** First menstrual cycle resulting from activation of the hypothalamic-pituitary-ovarian-uterine axis.
- Menopause** The final menstrual cycle in a woman's life.
- Perimenopause** The transition between menstrual cycles occurring at regular intervals to the final menstrual period characterized by irregular menstrual cycles and intermittent menopausal symptoms such as hot flashes.

Introduction and Definitions

The human menstrual cycle discussed in detail elsewhere in this Encyclopedia represents a sequence of biologic events beginning with the growth and development of a follicle containing an oocyte within the ovary. During this time of development hormones are secreted from the ovary that produce proliferation of the lining of the uterus while priming the hypothalamus and pituitary gland that eventually results in a “spike” in the release of both luteinizing hormone (LH) and follicle stimulating hormone (FSH). This hormonal spike in turn causes the release of the oocyte from the follicle (ovulation) which is then followed by the luteinization or transformation of the cells in the follicle into a corpus luteum. Progesterone and estradiol are secreted by the corpus luteum which causes “decidualization” of the lining of the uterus making it receptive for the implantation of an embryo that defines the initiation of pregnancy. When this occurs the pregnancy’s placental tissues begins to secrete human chorionic gonadotropin (HCG) which maintains the survival of the cells in the corpus luteum allowing them to continue to secrete estrogen and progesterone, and menses does not occur. Should an embryo not implant into the decidualized uterine lining, HCG is not produced and the corpus luteum ceases to secrete estradiol and progesterone and the rapid decline in the level of these hormones triggers vascular events in the lining of the uterus resulting in the shedding of its outer two layers. As this occurs the smooth muscle walls of the uterus begin to contract expelling the endometrial lining which is mixed with blood into the vagina and this is eventually discharged from the vagina and is now defined as menstrual blood. This entire process is defined as a menstrual cycle and the first time that this occurs in a woman’s life it is defined as the first menstrual period or menarche. Menopause is defined as the age at which the menstrual cycle no longer occurs.

Puberty and Menarche

Menarche represents the final physical event in a series of steps known as puberty. A growth spurt is the first physical event which is closely followed by secondary sex characteristic development typified by breast budding (thelarche) then the arrival of pubic hair growth (pubarche) and then lastly the onset of menses (menarche). Marshall and Tanner were among the first to carefully classify pubertal changes in 192 white British girls in 1969 (see [Table 1](#)). Genetics, overall health, social and physical environment are all thought to play a role in determining the onset of puberty. Depending upon the reference cited, in girls, the average age of menarche is between 12 and 13 years of age, with racial and ethnic differences affecting this. Black girls experience menarche earlier than white girls while Hispanic or Mexican American girls will have their menarche at ages intermediate to that of black and white girls. Menarche will usually occur within 2–3 years after the onset of breast development. As previously mentioned genetics appears to play a large role in determining the onset of menarche, but better social conditions and increased weight are also involved ([Zacharias and Wurtman, 1969](#)).

Table 1 Average age and standard deviation of pubertal events in 192 British girls

	Average age (years)	Standard deviation
Breast budding (thelarche)	11.15	1.1
Pubic hair (adrenarche)	11.69	1.21
Menarche	13.47	1.02

Data from Marshall, W. A. and Tanner, J. M. (1969). Variations in pattern of pubertal changes in girls. *Archives of Disease in Childhood* 1969, **44**, 291–303.

Puberty and menarche result from the changes in the hormone levels of estrogens, androgens and progestogens which begin to be secreted in increasing amounts from the ovaries and adrenal glands. Release of LH and FSH from the pituitary gland stimulates ovarian hormone secretion of estrogens and progestogens coupled with an increased ability of the adrenal gland to respond to adrenal corticotrophic hormone (ACTH) by secreting androgens. Pituitary release of LH and FSH is regulated by gonadotropic releasing hormone or GnRH which is released into pituitary portal blood by the hypothalamus.

At birth the hypothalamus and the pituitary gland are fully capable of synthesizing and releasing GnRH and LH and FSH respectively, but this does not occur until the onset of puberty. At birth the ovaries contain a fixed number of oocytes surrounded by granulosa cells contained in structures known as follicles which are responsible for the secretion of estrogen. Follicles at birth are fully capable of responding to stimulation by LH and FSH resulting in follicle growth and even ovulation. It is therefore believed that the initiation of puberty begins with the ability of the hypothalamus to release GnRH which prior to puberty has been under inhibition by numerous inhibitory factors. How these inhibitory factors are prevented from keeping the hypothalamus from releasing GnRH from birth until the onset of puberty remains an unanswered question.

Occurring independently with the activation of the hypothalamic pituitary axis is the release of androgens from the zona reticularis of the adrenal gland causing adrenarche which is followed by pubarche. Adrenarche usually precedes activation of the hypothalamic pituitary axis but may occur contemporaneously. Circulating levels of ACTH do not appear to change during this time and the identification of an adrenal androgen stimulating hormone has been sought, but not yet found. The cause of adrenarche also remains an unanswered question.

Disorders of Puberty

It is generally stated that the onset of puberty prior to age eight is considered to be precocious and is deserving of evaluation. Results from a pediatric office practice study conducted in 1997 called this recommendation into question (Herman-Giddens et al., 1997). In this study involving over 18,000 girls ages 3–12, over 90% were white while 9.6% were African American. At age seven, 27.2% of African American girls and 6.7% of white girls had breast and/or pubic hair growth. Nevertheless given how disturbing precocious breast development is emotionally to young girls and their parents, a medical evaluation is often requested and agreed to when breast development begins before age eight.

Precocious puberty may result by premature activation of the hypothalamic pituitary ovarian axis which is called central, complete, isosexual or true precocious puberty. Over 90% of the time no identifiable cause may be found (Chemaitilly et al., 2001) and the diagnosis is given as idiopathic and made by exclusion. However premature activation of the hypothalamic pituitary axis may result from brain lesions that either release GnRH or disturb the inhibition of GnRH so brain imaging is indicated in these patients.

Precocious puberty may also result from the secretion of steroid hormones by the ovaries or the adrenal glands independently of hypothalamic-pituitary stimulation and this is known as gonadotropin independent precocious puberty. Transient secretion of estradiol from autonomously functioning ovarian cysts is one of the most common causes of this which may result in a temporary increase in breast size and even vaginal bleeding. In contrast tumors of the ovary such as granulosa cell tumors or Leydig cell tumors may secrete estrogens and or androgens causing breast development and/or pubic hair growth which is not temporary and their existence must be ruled out.

Delayed puberty is usually defined as the lack of any secondary sex characteristic development by age 12 to 13 and by absence of menses by age 16. Failure of the hypothalamic pituitary axis to become active as a result of a deficiency in GnRH may be causative resulting from genetic defects or tumors. This is known as hypogonadotropic hypogonadism and is typified by low levels of LH and FSH and estradiol. Alternatively the ovaries may fail to function as a result of genetic conditions such as gonadal dysgenesis due to Turner's syndrome and this is typified by elevated LH and FSH levels and low levels of estradiol.

Menopause

The final menstrual period in a woman's life defines menopause, but this is only determined retrospectively and occurs on average between 50 and 51 years of age with a range of 40–60 years (Treloar, 1981). Menopause results from a decline in the number follicles within the ovaries with increasing age. At birth there are approximately 300,000–500,000 follicles in each ovary (Wallace and Kelsey, 2010) and during reproductive life it is estimated that roughly only 400–600 oocytes will be ovulated depending upon the length of time between the age of menarche and age of menopause with the remaining oocytes lost through a process known as atresia.

Prediction of the age of menopause has proven elusive as the rate of follicle loss within the ovary may be influenced by factors such as smoking, obesity and family history, but all over the world the average age of menopause has remained similar as a recent meta-analysis involving 170,000 women in 24 countries on 6 continents has demonstrated (Schoenaker et al., 2014). Distinct hormonal changes are seen as menopause approaches and the follicle number in the ovary begins to decline. Inhibin B levels, made by granulosa cells, fall as the number of granulosa cells declines due to the decline in the number of ovarian follicles. Inhibin B normally acts to inhibit pituitary secretion of FSH so as inhibin B levels decline, FSH levels begin to rise. Antimüllerian hormone or AMH is produced by the granulosa cells of small follicles and AMH is believed to thwart the ability of FSH to recruit resting into growing follicles.

With the rise in FSH as follicle numbers decline, there is a fall in the level of AMH, and the elevation of FSH is now believed to act more unimpeded by stimulating the recruitment of more resting follicles into growing follicles. This is believed to be the explanation for the rise in the follicular phase estradiol concentration seen in older ovulatory women (Hansen et al., 2005). In addition to these ovarian changes with aging, an aging effect on the hypothalamus and pituitary appears to be occurring as well. For example there is a 30% decrease in serum LH and FSH concentrations between ages 50 and 75 (Hall et al., 2000), coupled with a 22% decrease in the frequency of GnRH pulses (Hall, 2004) and with a 30% decrease in the pituitary's release of LH and FSH in response to GnRH stimulation (Shaw et al., 2010).

The decline in the number of what are called resting ovarian follicles is rather constant between menarche and the age of 37.5, but after that age the rate of follicle loss increases more than two-fold (Faddy et al., 1992). After age 37.5 either a faster rate of recruitment of resting into growing follicles by FSH occurs and/or there is excess atresia of the resting follicles has been proposed as explanations for this more rapid rate of follicle loss (Faddy and Gosden, 1996). It is believed that this more rapid rate of follicle loss ultimately results in only about 1000 resting follicles remaining at the time of the final menstrual period.

Perimenopause

As the final menstrual period approaches menstrual cycles may occur irregularly with 60%–70% of the cycles being anovulatory and the menstrual cycle interval becoming either short or prolonged (Van Voorhis et al., 2008). Measurement of LH, FSH, estrone conjugates and pregnanediol conjugates in daily morning urine samples taken from perimenopausal women reveals marked variation with elevations in LH and FSH and estrone conjugates and declines in pregnanediol conjugates (Table 2) (Santoro et al., 1996). This time period in life has been termed the perimenopause.

The duration of the perimenopause has not been well studied. In a recent large prospective clinical study of hormonal changes in women approaching their final menstrual period known as the Study of Women's Health Across the Nation (SWAN) Daily Hormone Study (DHS) less than 2% of the menstrual cycles appeared to be anovulatory 10 years before the final menstrual period whereas almost 80% of menstrual cycles were anovulatory 1 year prior to the final menstrual period (Santoro et al., 2017).

Vasomotor Symptoms

Hot flashes or flushes are vasomotor symptoms that occur during the perimenopause and menopause. These events are characterized by a sensation of warmth beginning at the head which then radiates down the neck and chest which is followed by perspiration and often concludes with a chill. Hot flashes frequently occur at night awakening a woman from sleep who then has difficulty falling back to sleep.

In the SWAN study it was reported that 60%–80% of women experience hot flashes during the menopausal transition (Gold et al., 2006), with some having hot flashes even earlier in life and others continuing to have them years afterwards (Barnabei et al., 2002).

The cause of hot flashes remains unknown but is associated with the decline in estrogen levels, and the administration of estrogen can prevent them. There are other risk factors for having hot flashes which include race, alcohol consumption, body mass index, exercise and smoking (Smith et al., 2016).

Hormone Replacement

Conjugated equine estrogens were made available to Canadians for treatment of menopausal symptoms by the Wyeth-Ayerst Company in the late 1930s. In 1942 the Food and Drug Administration granted permission for the Wyeth-Ayerst Company to market Premarin 1.25 mg for the treatment of menopausal symptoms to women in the United States (Stefanick, 2005). Estrogen has been proven over time to be the most effective drug treatment for hot flashes and in addition to conjugated estrogens, may be

Table 2 Range in urinary hormone levels in perimenopausal women compared to menstruating women

	Menstruating women (n = 11)	Perimenopausal women (n = 11)
Mean estrone (ng/mg Cr)	23–60	13–135
Integrated pregnanediol (μg/mg Cr)	1.6–12.7	1.0–8.4
Mean LH (IU/gCr)	1.1–4.2	1.4–6.8
Mean FSH (IU/gCr)	3–7	4–32

Hormones measured by immunoassays in first morning daily urine samples with results normalized in terms of creatinine (Cr).

Data compiled from Santoro, N., Brown, J. R., Adel, T. and Skurnick, J. H. (1996). Characterization of reproductive hormonal dynamics in the perimenopause. *The Journal of Clinical Endocrinology and Metabolism* **81**, 1495–1501.

given orally as micronized estradiol, or transdermally or transvaginally as estradiol. Estrogens may be safely given alone to women without a uterus, but if given alone to women with a uterus, endometrial hyperplasia and cancer may occur. If progestins are given with estrogen to women with a uterus there is almost no increased risk of uterine cancer.

In the 1980s retrospective studies reported that menopausal women who had taken unopposed estrogen hormone replacement had a reduced risk of dying from cardiovascular disease or from any other cause (Bush et al., 1983, 1987). These observations were confirmed by others and ultimately led to a clinical study funded by the Wyeth-Ayerst pharmaceutical company known as the HERS study or Heart and Estrogen/progestin Replacement Study (Hulley et al., 1998). Postmenopausal women with known heart disease were enrolled in this clinical trial to determine if estrogen plus progestin therapy alters the risk of cardiovascular events. Over 2700 women with coronary disease participated whose average age was 66.7 years and who were randomized to receive either conjugated equine estrogens plus 2.5 mg of medroxyprogesterone acetate daily or placebo. Results from this study were published in 1998 and surprisingly showed that postmenopausal women with heart disease who took hormone replacement had the same rate of cardiovascular events as the women who took placebo. In addition, the women who took hormone replacement (1380 volunteers) had more thromboembolic events, (34 vs. 12) than the women who took placebo (1383 volunteers).

Prior to the publication of the results from the HERS study, the National Institutes of Health began recruiting volunteers for a large prospective clinical study in 1993 that became known as the Women's Health Initiative or WHI study. In this study over 27,000 menopausal women volunteers with (16,608) and without (10,739) a uterus were recruited. Women with a uterus were given either conjugated equine estrogens (0.625 mg) combined with 2.5 mg of medroxyprogesterone acetate (Prempro) or placebo. For women volunteers without a uterus, they were given either 0.625 mg conjugated equine estrogens alone (Premarin) or placebo. The primary objective of this study was to determine if hormone replacement given to menopausal women could reduce their risk of death from heart disease. By design the study deliberately enrolled older women (2/3 of the participants were older than 59 years of age at the beginning of the study) with the mean age of volunteers being 63 (Prentice et al., 1998).

The estrogen and progestin arm of the study was stopped after 5.2 years because no benefit from a reduction in cardiovascular events was demonstrated but an increased risk in breast cancer was observed (Writing Group for the Women, 2002). The estrogen only arm of the study was stopped after 6.8 years of treatment because a reduction in cardiovascular events was not seen while an increase in risk of ischemic stroke was observed (The Women's Health Initiative Steering Committee, 2004). Risk of breast cancer was not increased in the estrogen arm of this study, but was almost significantly decreased, a fact that did not receive much public attention.

Following the publications of these findings from the WHI many women stopped taking hormone replacement for treatment of their menopausal symptoms. Results from human and subhuman primate studies then led to the development of what is now known as the "timing hypothesis" to reconcile the results of the WHI with previous observational data (Clarkson, 2002). In brief this hypothesis states that if hormone replacement is begun at the time of menopause it may protect coronary vessels from atherosclerotic vascular disease. But if hormone replacement is begun many years after menopause it may not only not protect coronary vessels from atherosclerotic vascular disease, but may worsen it. Over time there has been a gradual re-evaluation of the risks and benefits of hormone therapy with a consensus now beginning to form that for younger women there is a favorable risk-benefit profile to the use of hormone replacement to treat menopausal symptoms (Lobo, 2017). Overall, it is recommended that patients with menopausal symptoms discuss the risks and benefits of hormone replacement therapy with their physician and that treatment should be individualized.

Reproductive Senescence in the Female

Introduction

With advancing age there is a decline in a woman's overall fertility and fecundity. Historical reports examining fecundity from the 16th to 19th century have documented that women who married late in life, after the age of 35, were more likely to die childless. Recent studies have shown that the decline in fertility begins at approximately the age of 30. Women then undergo a period of menstrual cycle irregularity known as the menopausal transition starting around age 46. With a permanent ending of menstruation at approximately 51, women enter menopause. Classically defined, natural menopause is the permanent cessation of menstruation recognized to have occurred after 12 consecutive months of amenorrhea, for which no other obvious pathological or physiological cause could be determined. These age related changes are due to alterations in ovarian function, dominated by a gradual decrease in both the quantity and the quality of the egg or oocytes, which play an essential role in the transition from a normal fertile menstrual cycle to reproductive senescence.

Ovarian Aging

To fully comprehend the changes in the ovarian follicular pool that occur throughout a woman's lifespan, one has to understand the dynamics of follicular growth and the accompanying hormonal fluctuations. As the ovary develops during the fetal period, it has about 6–7 million eggs or oogonia. During gestation these oogonia either form primordial follicles that are composed of the oocyte surrounded by a flattened layer of granulosa cells or are removed from the ovary through a process of apoptotic programmed cell death known as atresia. Primordial follicles are the precursors for follicles which will go on to develop and ovulate a mature egg which can be fertilized and lead to pregnancy. At birth the number of primordial follicles has declined to about 1–2 million, mainly through atresia. This atretic process continues after birth, and at puberty a woman has approximately 300,000 primordial follicles (Fig. 1). This pool of primordial follicles is known as the ovarian reserve and reflects a woman's reproductive potential and overall fertility in the coming years.

Primordial follicles will either continue to undergo atresia or will be activated from the quiescent primordial follicle pool to undergo follicular growth and development through a process known as folliculogenesis. Folliculogenesis can be broken down into three broad and successive phases. The first phase is initiation or activation of the quiescent primordial follicle, which occurs from birth to the age of menopause and is independent of support from the gonadotropins, follicle stimulating hormone (FSH) or luteinizing hormone (LH). Upon initiation, the granulosa cells of the primordial follicle change from a squamous shape to become

Fig. 1 Schematic representation of the age related changes and corresponding reproductive events in women. The number of primordial follicles present in the ovaries from birth until menopause is illustrated along with the quality of oocytes across the reproductive lifespan. Reproduced with permission from Broekmans, F. J., Soules, M. R. and Fauser, B. C. (2009). Ovarian aging: mechanisms and clinical consequences. *Endocrine Reviews* 30(5), 465–493.

cuboidal and the oocyte enlarges as the follicle becomes a primary follicle. With continued granulosa cell proliferation and differentiation, there is the development of the theca cell layer and a basement membrane as these primary follicles develop to become secondary and tertiary preantral follicles. The second stage known as recruitment requires tonic stimulation by FSH. At this time, FSH drives continued granulosa cell proliferation as the preantral follicles develop a fluid filled cavity forming the antral follicle. There is an increase in vascularization of the theca supplying the follicle with various growth factors which further drives follicular growth and the production of estradiol. The third and final stage of follicular growth requires luteinizing hormone (LH), which sets in motion a cascade of intracellular signaling pathways in the large preovulatory follicle leading to oocyte release through the process of ovulation.

By the time a woman reaches her late teens to early 20s she has entered into a fertile period characterized by regular monthly menstrual cycles (Fig. 1). During the early follicular phase of a woman's 28 day menstrual cycle, a number of preantral follicles are recruited through the actions of FSH. FSH stimulates granulosa cell proliferation, growth of the follicles and the production of estradiol and the inhibins A & B. Increasing levels of inhibin B during the early follicular phase feedback on the hypothalamic pituitary axis to inhibit FSH. In the face of declining levels of FSH, one follicle becomes dominant while the remaining cohort of growing follicles undergo atresia. The remaining dominant follicle is responsible for a rapid increase in estradiol during the latter stages of the follicular phase of the menstrual cycle which in turn decrease inhibin B from the ovary. At the midpoint of the cycle, elevated levels of estradiol act to stimulate the production of both FSH and LH from the hypothalamic pituitary axis along with an increase in inhibin A & B. The peak of LH sets in motion a cascade of events that result in ovulation and the transformation of the ruptured dominant follicle into a corpus luteum. The midcycle increase in FSH and inhibin A are thought to contribute to oocyte maturation and/or ovulation. The corpus luteum is responsible for estradiol, progesterone and inhibin A production during the midluteal phase of the cycle. Without the appropriate signals of pregnancy, the CL undergoes regression and there is a subsequent fall in progesterone, estradiol, and inhibin A from the CL which allows the levels of FSH to begin to rise again at the onset of the subsequent menstrual cycle. These cellular and hormonal changes associated with normal follicular growth, such as FSH and inhibins, have been used as important indicators of reproductive aging as described below.

From the pool of about 200,000 primordial follicles at puberty only approximately 60,000 remain at the age of 30. In addition to the loss of follicles that occurs, there is a decline in the quality of the oocyte as reflected by an increased incidence of miscarriages and chromosomal alterations that occur after 35 (Fig. 1). This is attributed to an increase in meiotic nondisjunction of the chromosomes during meiosis resulting in an increasing rate of aneuploidy in older women. Also around this time, there is an increase in FSH as the follicular pool begins to shrink. This increase in FSH occurs because factors produced by follicles which inhibit FSH secretion from the hypothalamic–pituitary axis, such as inhibin B and anti-Müllerian hormone (AMH), begin to decline. This decline in negative FSH regulators results in an increase in circulating levels of FSH in an attempt to increase the growing follicular pool. The elevated FSH promotes inappropriate maturation of the follicular granulosa cells resulting in the demise of these follicles by atresia. This vicious cycle results in a loss of additional follicles which continues to drive increasing levels of FSH to attempt to compensate for the diminished growing follicular pool.

There is evidence of internal self regulation of the size of the ovarian pool by local ovarian factors. As the pool of primordial follicles is depleted and the number of developing follicles declines, there is compensation by the ovary to increase the number of primordial follicles activated. Previously it was thought that at around the age of 35–38, the number of primordial follicles falls below 25,000 and the rate of follicle loss is accelerated. However, using stereologic techniques to determine ovarian follicle numbers there appears to be no sudden change in primordial follicle number but rather a consistently increasing rate of follicle loss as women age. This model for primordial follicle loss may be more biologically plausible as the ovary tries to compensate for the diminishing follicular pool.

With continued follicle loss a woman enters the menopausal transition of the perimenopausal period characterized by the onset of menstrual cycle irregularity. This transition period has been divided into an early and late stage. The early stage occurs when there are two or more cycles with a difference in length of greater than 7 days. This cycle irregularity leads to increasing periods of amenorrhea. The onset of the late stage of the perimenopausal period occurs when there are 60 or more days of amenorrhea. This menopausal transition, from the onset of menstrual cycle irregularity to menopause, is reported to be occur around the age of 46 (range 34–54 years) and lasts approximately 6 years. As the primordial follicle pool continues to be depleted and approaches 1000 follicles, a woman reaches menopause which occurs around the age of 51 (range 40–60 years). The time it takes to reach a pool of 1000 follicles from the critical threshold of about 25,000 follicles seems to be fairly constant, at approximately 13 years leading to a “fixed interval” hypothesis between the age at onset of cycle irregularity and the age at menopause.

Premature Ovarian Failure

Premature ovarian failure (POF) in women, also known as primary ovarian insufficiency (POI), is characterized by the absence of normal ovarian function due to depletion of the primordial follicle pool before the age of 40. POF is classified as an absence of menses for at least 4 months in combination with elevated FSH levels exceeding 40 IU/L before age of 40. POF affects approximately 1% of women below the age of 40% and 0.1% before the age of 30 (approximately 700,000 and 70,000 women respectively).

In addition to the decline in fecundity in women with POF, the loss of follicles results in a loss of ovarian hormones that has far reaching health consequences. Estradiol produced by the follicle during the late stage of the follicular phase and during the midluteal phase of the menstrual cycle provides numerous health benefits. Estradiol is responsible for maintenance of bone mineral density throughout life, preventing atherosclerosis, and improving mental health by attenuating mood and decreasing depression.

Thus, the premature loss of follicles results in an increased incidence of stroke and cardiovascular mortality, osteoporosis and bone fractures, and certain cancer risks such as colorectal cancer. To circumvent these health risks, hormonal replacement therapy using combined estrogen and progesterone medications are currently used to circumvent the loss of ovarian steroids and clinically manage these women.

Factors Influencing Ovarian Aging

Multiple factors appear to influence ovarian aging. These include genetic, iatrogenic, immunologic, metabolic, and infectious elements as well as exposure to environmental factors. The strong link to a genetic component has been demonstrated in studies examining the age when a woman undergoes natural menopause. Women experiencing relatively early menopause have mothers or will have daughters who also were likely to have become menopausal early in life as well. Likewise, it has been proposed that the size of the pool of primordial follicles, the proportion of these follicles that undergo atresia, as well as the rate of follicle activation is genetically determined.

Genetic Factors

Women with POF have provided a unique clinical model to begin to explore the genetic changes associated with alterations in ovarian aging. Early studies examined candidate genes associated with fetal formation of the primordial follicle, initial recruitment from the primordial follicle pool or follicular growth and development in women with POF. POF has been linked with mutations in genes associated with hormone and hormone actions (FSHR, LHR, PGRMC1, AMHR2, CYP17, CYP19), genes that regulate the early stages of oocyte development and ovarian formation (NOBOX, FIGLA, LHX8) as well as genes that impact initial folliculogenesis (BMP15, GDF9, GPR3). For example, polymorphisms in the AMH receptor 2 gene, which would decrease AMH signaling, have been associated with an earlier age at menopause in two large cohorts of Dutch postmenopausal women. Altering AMH signaling could potentially weaken the inhibition of initial follicle recruitment, resulting in a possible increased rate of follicle loss thereby advancing the age at menopause.

Abnormalities of the X chromosome have long been recognized as a frequent cause of many forms of familial POF. The more common of these include Turner's syndrome, triple X syndrome, Fragile X, and BMP15 variants. Women with Turner's syndrome, which is the loss of one X chromosome, have a loss of oocytes during the early stages of meiosis and ovarian development. Mutations of a trinucleotide repeat sequence in the fragile X mental retardation 1 (FMR1) gene is one of the most common genetic abnormalities associated with POF (incidence of 4%–15%). Although the mechanism is unclear, the FMR protein may play a role in early ovarian development by regulating oogonia proliferation which would determine the set point of the initial size of the ovarian reserve.

There are other autosomal mutations that have been linked with POF. Blepharophimosis, ptosis, epicanthus inversus syndrome (BPES) is an autosomal dominant eyelid malformation associated with POF. Mutations in the forkhead transcription factor L2 (FOXL2) are linked with BPES and may influence the follicular pool through the actions of FOXL2. FOXL2 regulates AMH expression as well as estradiol signaling through the estrogen receptor B (ESR2) which could potentially impact the ovarian follicular pool. Other alterations such as the ataxia telangiectasia mutated gene (ATM) have been associated with primordial germ cell development. Mutations in Factor V Leiden and apolipoprotein E-2 and their association with age at natural menopause has led to the hypothesis that genetically altered vascular support has long-term effects on ovarian follicle depletion. Thus, there are a large number of genetic alterations that have been reported to be associated with POF and appear to act through a variety of different mechanisms to affect the ovarian follicular pool.

More recently, genome wide association studies (GWAS) have examined possible genetic determinants and POF. A GWAS approach compares the DNA of women with POF to the DNA of women who do not exhibit POF to identify single nucleotide polymorphisms (SNPs) associated with POF. An advantage to the GWAS approach is that a non-candidate driven approach provides a basis to examine genetic changes across the genome as opposed to single gene specific candidate driven studies. Early genome-wide association analysis has revealed a candidate region linked to the ADAMTS19 and PTHB1 genes. Ongoing studies are identifying single nucleotide polymorphisms that are possible candidate mutations for POF. These studies provide evidence that the age at which the menopause occurs may vary among individuals and may be determined by genetic factors.

Environmental Factors

Many environmental and lifestyle factors have been suggested to negatively influence the ovarian follicular pool thereby leading to POF, such as smoking and environmental chemical exposure. Meta-analysis studies of environmental pollutants and POF have revealed that tobacco, pesticides and endocrine disrupting chemicals were the most reported substances having a negative impact on ovarian function resulting in an increased follicular depletion leading to an earlier age of menopause onset.

Cigarette smoking has been shown to be one of the most common and important factors resulting in a reduction of the primordial follicle pool where compounds present in tobacco enhance follicle damage and premature ovarian failure. Cigarette smoke contains more than 4000 chemicals including hydrocarbons, alcohols, phenols, aldehydes, and heavy metals. Hydrocarbons can act on the aryl hydrocarbon receptor of the ovary and activation of this receptor decreases oogonia proliferation in human fetal ovaries.

Endocrine disrupting chemicals include the phthalates and bisphenol A. Phthalates are chemicals that are ubiquitous in the environment and are currently used in the manufacture of plastics and consumer products such as clothing, children's toys and

cosmetics. Phthalates act to decrease the number of primordial follicles in mice and decrease antral follicles in women. Bisphenol A (BPA) is found in plastics used for food packaging, the epoxy resins that coat the interior of metal containers and beverage cans as well as papers receipts. BPA acts at the estrogen receptor to mimic the actions of estrogen and like the phthalates, BPA can decrease the number of primordial follicles in rodent studies.

Women undergoing chemotherapy or radiation therapy for cancer treatment are often infertile or sterile. Alkylating agents such as cyclophosphamide act to deplete the pool of primordial follicles. The mechanism of action varies depending upon the specific agent but is thought to be directed to the oocyte or the surrounding supporting granulosa or theca cells.

Predictors of Ovarian Aging

The loss of follicles and diminution of the follicular pool is only recognized at the late stages by alterations in menstrual cycle regularity. Because of this inability to accurately predict the vitality of the follicular pool before this menopausal transition, there has been a keen interest in the development of diagnostic markers of the ovarian follicular reserve and numerous potential markers have been explored.

Follicle Stimulating Hormone

As noted above, levels of FSH begin to increase as the primordial pool is depleted, long before the onset of menstrual cycle irregularity is observed. This increase in FSH levels begins and continues to rise during the perimenopausal period making it a predictor of the size of the follicular pool. FSH has remained a keystone in the classification of the current phases of reproductive aging according to the Stages of Reproductive Aging Workshop. However, during the regular menstrual cycle FSH demonstrates a cyclic pattern of secretion with an increase during the luteal period which acts to recruit follicles for the next menstrual cycle and another midcycle surge of FSH. Thus, there are naturally occurring changes in FSH secretion throughout the menstrual cycle. With aging, this naturally occurring increase in FSH during the luteal period becomes elevated with a loss of follicles. Using this rise in basal levels of serum FSH during the luteal period when paired with a woman's chronological age provides a crude surrogate marker of biological ovarian age. However, the capacity of FSH to predict the timing of future changes in the reproductive state (i.e., occurrence of menopause or the menopausal transition) has been reported to be weak, stimulating interest in other biomarkers of ovarian aging.

Antral Follicle Count (AFC)

The pool of primordial follicles is too small to observe by conventional imaging techniques such as ultrasound or transvaginal sonography (TVS) imaging. However, this pool of primordial follicles gives rise to follicles that develop into fluid filled antral follicles which can be imaged and counted. Histological analysis has demonstrated that the number of primordial follicles in the ovary is correlated with the number of antral follicles at all ages of a woman's life. This correlation is not a 1:1 association but rather a percentage of the primordial follicle pool. Since the decline in primordial follicle numbers parallels the decrease in size of the antral follicle pool with female aging, antral follicle count represents a better marker than either chronological age or basal FSH for assessing the ovarian biological age and has become an acceptable standard for assessment of the ovarian reserve.

Inhibin B

Inhibin B is a peptide hormone that is produced primarily by growing antral follicles that are responsive to FSH. As the follicle continues to grow and become dominant, inhibin B secretion declines. As the growing pool of antral follicles decreases during aging, levels of inhibin B are diminished. Studies in women have demonstrated that decreased inhibin B secretion is associated with elevated FSH levels and decreased oocyte quality and fertility potential. Thus, inhibin B has been used as a predictor of ovarian reserve. However, the late appearance of inhibin B in the menopausal transition has led to the suggestion that it may be a better indicator of ovarian activity than of ovarian reserve, due to its direct link with growing follicles.

Anti-Mullerian Hormone (AMH)

Anti-Mullerian hormone or AMH is a peptide hormone that is produced predominately by preantral and early antral follicles. AMH secretion begins when follicles differentiate from the primordial to the primary stage and declines when the follicle has reached the midantral stage (diameter of 2–6 mm). Granulosa cells are the predominate source of AMH production. Studies have demonstrated that with the decrease in the number of antral follicles with age, AMH serum levels also decline and will invariably become undetectable near menopause. Because AMH does not exhibit cyclic changes across the menstrual cycle, AMH levels have gained favor as a serum marker for the ovarian follicular reserve and may provide an index of age at menopause.

Menopausal Consequences on Overall Health

The age of the onset of menopause has remained fairly constant at approximately 51 years of age. However, life expectancy for women born in the United States has continued to increase. In 1917 the average life expectancy was 56 years where a woman would

live only 3–5 years after menopause. Women now have an average life expectancy of approximately 87 years resulting in women spending about one third of their life in a postmenopausal hypoestrogenic state. The loss of follicles and the accompanying loss of hormonal steroids during the late stage of the follicular phase and during the midluteal phase of the menstrual cycle have far reaching health consequences.

Early changes associated with the onset of menopause include vasomotor symptoms comprising hot flushes and night sweats. The duration and severity of these vasomotor changes that women experience vary among individuals. Symptoms can develop during the menopausal transition, during menopause, or after menopause and can last for a few years or for extended periods in the postmenopausal period. Night sweats often lead to insomnia and overall fatigue. The mechanism behind the onset of hot flushes and night sweats appears to involve the central nervous system, possibly linked to a narrowing of the thermoregulatory set point in women.

Women are protected from cardiovascular problems (ischemic heart disease, stroke and other heart diseases) mainly because of the protective role of estrogens against atherosclerotic disease. Estrogens maintain the flexibility of the arterial wall by acting on the endothelial and smooth muscle cells comprising the blood vessel. In the postmenopausal period, arterial vessels become more rigid decreasing blood flow. With the loss of estrogen, the risk of cardiovascular problems in postmenopausal women grows and becomes similar to that of men by the age of 75.

Estrogens are responsible for maintenance of bone mineral density throughout life. Estrogens act to stimulate osteoblasts, the cells responsible for bone formation. In the years after menopause, the dynamics of bone density are shifted away from the balance of bone formation and resorption toward bone resorption. This results in osteoporosis leading to bone fragility and fractures.

With the onset of menopause there are changes in cognition, mood and an increase in depression. Observational studies suggest that the symptoms of depression are more frequent in the perimenopause, particularly in the late menopausal transition with a peak around the last menstrual period. Animal studies have convincingly demonstrated a protective role for estradiol in preventing these CNS changes. However, studies in women have provided conflicting evidence about the benefit of estrogen replacement in preventing many of these neurocognitive and mood changes.

Genitourinary syndrome of menopause describes the changes in the vagina, vulva and bladder associated with loss of estrogen and other hormones. Estrogen acts to lubricate and keep the vagina flexible. A loss of hormones results in vaginal dryness and dyspareunia or painful intercourse, which in turn results in lower libido and hypoactive sexual desire disorder. Other genitourinary changes associated with menopause include genital dryness, burning or irritation as well as an increased urgency to urinate, pain with urination and recurring urinary tract infections. Thus, the loss of follicles and the changing hormonal milieu results in an increased incidence of stroke and cardiovascular mortality, osteoporosis and bone fractures, and certain genitourinary changes. To circumvent these health risks, hormonal replacement therapy using combined estrogen and progesterone medications are currently used to circumvent the loss of ovarian steroids and clinically manage many of these symptoms.

Glossary

Actual efficacy (also called practical efficacy or typical use efficacy) Contraceptive efficacy when a method is used by people not involved in clinical trials.

Breakthrough bleeding Unanticipated or unscheduled bleeding or spotting, originating in the uterus and similar to menstrual bleeding.

Efficacy Effectiveness of a contraceptive method, the expected number of women who do not get pregnant in a group of 100 women using the method for an entire year.

Estrogens A group of structurally related steroid hormones that act at estrogen receptors.

Endometrium Lining of the uterus, is lost with menstruation.

Intrauterine device (IUD) T-shaped device placed in the uterus for contraception.

Long-acting reversible contraception (LARC) Contraceptives that remain in place and provide long-lasting but reversible contraceptive action.

Luteinizing hormone (LH) A protein hormone produced by the anterior pituitary.

Progestins A group of structurally related steroid hormones that act at progesterone receptors.

Subcutaneous Under the skin.

Synthetic Human-made in the laboratory, not found in nature.

Theoretical efficacy Contraceptive efficacy during perfect use, usually determined in clinical trials.

Transdermal Across the skin.

Opportunities for Female Contraception

Fertility requires interaction between the oocyte and the sperm. During intercourse, ejaculation results in the release of hundreds of millions of sperm in the vagina, near the opening of the uterine cervix. Sperm penetrate the cervical mucous and move through the lumen of the uterus into the oviduct (also called the fallopian tube or uterine tube). The oocyte (also known as the egg or ovum) leaves the ovary at ovulation, enters the oviduct through the fimbria, and is propelled through the oviduct and toward the uterus by the movement of cilia and muscle contractions of the oviduct. Fertilization, the fusion of oocyte and sperm, occurs in the oviduct. After fertilization, the single cell embryo, or zygote, continues to move through the oviduct and toward the uterus as the early cell divisions of embryonic development get underway.

The oocyte develops within the ovarian follicle. The mature ovarian follicle (also called a dominant, ovulatory, or Graafian follicle) produces large amounts of the steroid hormone estrogen, which enters the circulation. High serum levels of estrogen stimulate the anterior pituitary to release of a large amount or “surge” of LH. This surge of LH acts at the ovarian follicle to initiate a series of events that culminate in ovulation, including rupture of the follicle and release of the oocyte. After ovulation, the ruptured follicle is transformed into a corpus luteum and produces large amounts of the steroid hormone progesterone.

Estrogen and progesterone stimulate changes in the woman's body that affect fertility. Estrogen stimulates the oviduct to produce fluid and increases muscle contractions, which assist the movement of the oocyte from the fimbria and toward the uterus. Estrogen results in the production of a thin, watery cervical mucous, which is easily penetrated by sperm moving from the vagina into the uterus and toward the oviduct. Estrogen causes the endometrial lining of the uterus to regrow after menstruation. In turn, progesterone reduces fluid secretion and muscle contractions in the oviduct, limiting oocyte entry into the oviduct and transport through the oviduct. Progesterone increases the viscosity of cervical mucous, reducing sperm transit from the vagina to the uterus and oviduct. Progesterone also acts at the endometrial lining of the uterus to prepare for implantation and pregnancy. Falling progesterone levels after a period of progesterone exposure causes shedding of the uterine endometrium or menstruation. However, continuous exposure to progesterone prevents growth and development of the uterine endometrium.

Structure and function of the female reproductive tract offers many opportunities to intervene and prevent fertility (Table 1). Barrier methods prevent movement of sperm from the vagina, thereby preventing fertilization. Occlusion of the oviducts also prevents sperm–oocyte interaction. Spermicides damage or destroy sperm cells, so sperm are unable to fertilize the oocyte. Chemical spermicides and the intrauterine device (IUD) utilize this approach to fertility prevention. Hormonal contraception disrupts many aspects of female reproductive function, ultimately reducing fertility. Behavioral methods to prevent pregnancy include abstinence, periodic abstinence, and withdrawal of the penis from the vagina prior to ejaculation.

Table 1 Most effective contraceptive method used in the past month by US women in 2012

<i>Method</i>	<i>Number of users</i>	<i>Percent of women aged 15–44</i>
The pill	9,720,000	16.0
Female permanent contraception	9,443,000	15.5
IUD	3,884,000	6.4
Withdrawal	1,817,000	3.0
Progestin injection	1,697,000	2.8
Vaginal ring	759,000	1.2
Periodic abstinence	509,000	0.8
Progestin implant	492,000	0.8
Hormone patch	217,000	0.4
Emergency contraception	91,000	0.2
Other female methods ^a	133,000	0.3
Male methods ^b	8,823,000	14.5
No method; at risk of unintended pregnancy	4,175,000	6.9
No method; not at risk of unintended pregnancy	19,126,000	31.4

^aIncludes diaphragm, female condom, spermicide, cervical cap, and sponge.

^bIncludes male condom and male sterilization (vasectomy).

Selection of a Contraceptive Method

There are many considerations for selection of a contraceptive method. Permanent contraception eliminates the possibility of all future pregnancies. Reversible contraceptives can prevent pregnancy in the short-term while preserving long-term fertility. Contraception can be used with the intention of preventing all pregnancies. However, reduction of overall family size by increasing time interval between pregnancies can also be achieved with contraception. When selecting a contraceptive method, a woman may also consider safety, effectiveness, cost of the method, how often the user needs to employ the contraceptive, whether the method requires action immediately before intercourse, side effects caused by use of the method, impact on the sexual experience, if her partner should be involved, and whether a clinician must be consulted to acquire or employ the method properly.

Steroid Hormones as Components of Contraceptives

Steroid hormones, including estrogen and progesterone, are important to the proper function of the female reproductive system. High levels of estrogen are characteristic of the first half of the menstrual cycle. During this period of follicle growth and maturation, estrogen supports the health of reproductive tract organs including the oviduct, uterus, and cervix. Estrogen also increases the number of progesterone receptors in these organs. After ovulation, the follicle transforms into the corpus luteum, which produces large amounts of progesterone. Reproductive tract organs respond to progesterone via progesterone receptors to decrease oviductal motility, thicken cervical mucous, and prepare the uterine endometrium for possible implantation. Progesterone also decreases the number of estrogen receptors in these tissues, decreasing the effects of estrogen and limiting the ability of estrogen to increase progesterone receptor numbers.

Progesterone or a progesterone-like molecule (progestins) is an essential component of all hormonal contraceptives. As described earlier, progesterone decreases many reproductive tract functions required for fertilization. Progesterone also decreases estrogen action at these tissues due to the decrease in estrogen receptors. Finally, progesterone prevents the release of surge levels of LH, so LH cannot initiate events within the ovary that lead to ovulation, including follicle rupture and release of the oocyte. Many hormonal contraceptives also include an estrogen to reduce unwanted and unpredictable uterine bleeding (often called breakthrough bleeding) and to help maintain the overall health of nonreproductive tissues, such as the bone, skin, and heart.

The development of synthetic, orally active progestins and estrogens was a major advance in female contraception. Progestins, including progesterone and 17 α -hydroxyprogesterone, and estrogens, including estradiol and estrone, are produced in the body primarily by the ovary. For a contraceptive, circulating levels of steroid hormones must be maintained at relatively constant levels. Natural progestins and estrogens circulate in the bloodstream for several hours after production and then are removed from circulation by the liver and kidneys. Natural steroid hormones are damaged by passage through the digestive system, so oral administration of progesterone and estrogen is impractical. For these reasons, use of naturally occurring steroid hormones would require frequent readministration.

These limitations were overcome with the development of synthetic progestin and estrogen molecules. Synthetic hormones maintain bioactivity after oral administration, passage through the digestive system, and uptake into the circulation. Synthetic hormones can also be administered via transdermal patches, subcutaneous implants, and injections. Synthetic hormones remain

in the circulation longer than natural steroids because their chemical structure prevents rapid modification, conjugation, and elimination in the liver and kidneys. Synthetic progestins and estrogens activate progesterone receptors and estrogen receptors, respectively, but often with higher potency than natural progesterone and estrogen. These are just some of the reasons that synthetic progestin and estrogen molecules are used as components of hormonal contraceptives.

Synthetic progestins that bind to progesterone receptors but block activity of progesterone receptors are called antiprogestins. These synthetic hormones can prevent fertility by disrupting the activity of progesterone in reproductive tissues. The most common contraceptive actions of antiprogestins are to (1) reduce or eliminate the ovulatory LH surge and (2) block necessary actions of progesterone within the ovulatory follicle prior to ovulation. Actions of antiprogestins in the uterus to disrupt implantation or early stages of placenta development are not contraceptive since these actions occur after fertilization has taken place.

Hormonal Contraception: Combination Hormonal Contraceptives

The first combination oral hormonal contraceptive, commonly known as The Pill, contained large amounts of a synthetic estrogen and a synthetic progestin. Since The Pill was introduced in 1960, there has been a steady decrease in the concentration of the progestin and the estrogen in oral contraceptive products. Products with lower steroid doses remain highly effective at preventing pregnancy with a substantial reduction in side effects, especially deep vein thrombosis and other cardiovascular events.

The regimen of oral hormonal contraceptives was initially designed to mimic the 28-day interval between menstruations. A common formulation involved 21 days of steroid-containing pills, with 7 days of placebos to allow circulating steroid hormone levels to fall and permit menstruation. Changes in duration of administration have resulted in a variety of regimens, including 24 days of steroids with 4 days of placebo, continuous steroid administration for 84 days, and continuous steroid administration for 365 days. Continuous pill use increases the incidence of no menstrual bleeding, which is highly acceptable to some women. However, unscheduled endometrial bleeding, known as breakthrough bleeding, can occur with any steroid regimen. Oral hormonal contraceptives containing estrogen and progestin have a pregnancy rate of 1%–4% in well-controlled clinical trials (Table 2).

Hormonal contraception is also available in nonpill forms. Estrogen plus progestin contraceptives can be administered via a transdermal delivery system, vaginal ring, or injection. Transdermal and vaginal delivery use a regimen of 21 days of active hormone and 7 days of no hormone to permit menstruation and approximate the length of the typical menstrual cycle. The monthly injection has a duration of efficacy of 28 days and must be administered every 4 weeks. The contraceptive efficacy of these methods is very high, with pregnancy rates of 1%–2% in well-controlled clinical trials.

The lower dose combination oral hormonal contraceptive products in current use are relatively safe. The principal significant adverse events resulting from use of combination oral hormonal contraception are increased incidence of venous thrombosis in the leg and pulmonary emboli. Use of a modern, low-dose combination oral hormonal contraceptive doubles a woman's risk for these cardiovascular events. However, the risk of cardiovascular events associated with these contraceptives is much lower than the risk of cardiovascular events associated with pregnancy. Women with certain inherited clotting disorders or a family history of certain cardiovascular disorders should consider other methods of contraception. Women over the age of 35 who have hypertension, have diabetes mellitus, or smoke cigarettes are at increased risk of stroke and myocardial infarction. In women without these risk factors, low-dose combination oral hormonal contraceptives can be used during a woman's reproductive years up to menopause without a significant age-related increased risk of cardiovascular disease.

Table 2 Pregnancy rates (number out of 100 women) during the first year of continuous use of the contraceptive method

<i>Method</i>	<i>Perfect use^a</i>	<i>Typical use</i>
Intrauterine device—levonorgestrel	0.1	0.1
Progestin implant	0.1	0.1
Progestin injection	0.3	0.3
Female permanent contraception ^b	0.5	0.5
Intrauterine device—copper	0.6	0.8
Oral combined hormonal	1	9
Oral progestin only	0.5	9
Withdrawal	4	19
Diaphragm with spermicide	6	20
Female condom	5	24
Periodic abstinence	5	25
Spermicide alone	6	26
No contraception	85	85

^aFrom product label or other information.

^bIncludes both surgical and nonsurgical methods.

Side effects include nausea, weight gain, mood disturbances, breast tenderness, headache, and unscheduled endometrial bleeding. These side effects may disappear or improve with continued use. However, for some women, side effects are significant and result in discontinuation of the method.

Typical failure rates for oral, transdermal, vaginal, or injectable combined hormonal contraceptives are approximately 9% and are likely the result of compliance errors by the user.

Hormonal Contraception: Progestin-Only Methods

Progestins inhibit the pituitary LH surge and, therefore, prevent ovulation as the principal mechanism of action. Additional actions of progestins to decrease the likelihood of fertilization contribute to the high effectiveness of progestin contraceptives. Clinical testing of synthetic progestin-only oral methods reports pregnancy rates of <1%. Typical user's failure rates for daily oral progestin-only methods are about 9%.

Contraceptive efficacy can be enhanced with delivery systems that provide extended duration of progestin activity and minimize or eliminate the need to remember to use the contraceptive. Progestins can be delivered by subcutaneous implants, vaginal ring, IUD, and injection. These methods are termed long-acting reversible contraceptives (LARCs). Subcutaneous implants, vaginal rings, and IUDs contain the progestin within a plastic membrane. The plastic membrane controls the amount of hormone released each day, resulting in a duration of action of 1 month to 8 years, depending on the individual device. The high efficacy associated with these methods is due, in large part, to the fact that the user does not need to remember to use the method on a daily or weekly basis. Implants, vaginal rings, and IUDs can be removed for relatively rapid return to fertility. However, injections form a subcutaneous depot of progestin that cannot be removed. As such, return to fertility after discontinuing injections can require up to a year. The delivery system has a significant effect on typical user pregnancy rates with progestin-only contraceptives, making LARCs highly effective. Theoretical and typical user pregnancy rates are both <1%.

The primary side effect of progestin-only contraceptives is unscheduled and irregular endometrial bleeding. This bleeding does not reflect a malignancy but is the principal reason for discontinuation of progestin-only methods. Progestins have none of the estrogen-related significant side effects, most importantly blood clots. For this reason, hormonal contraceptives that contain progestin with no estrogen may be appropriate for women at higher risk of cardiovascular issues, including older women and women who smoke. Progestin-only contraceptives are appropriate for breastfeeding women since the estrogen component of combined hormonal contraceptives interferes with lactation.

Intrauterine Devices

The IUD is a T-shaped plastic device that is placed within the lumen of the uterus, such that the arms of the "T" point toward the oviducts, with the lower end of the "T" pointing toward the cervix. The plastic of the IUD has contraceptive action, creating a sterile inflammatory response that has spermicidal activity. However, all currently available IUDs are designed to have enhanced activities. Some IUDs include copper wound on the arms and stem, which enhances the spermicidal activity. Other IUDs include a progestin within the stem of the device. With progestin-releasing IUDs, locally elevated progestin within the uterine lumen decreases endometrial development and reduces or eliminates menstruation; progestin also decreases uterine contractions to reduce the rate of spontaneous expulsion of the IUD.

An IUD should be placed in the uterus by an experienced clinician. For insertion, the arms of the T are folded parallel to the stem of the device and held in place with an inserter. The inserter is introduced through the cervix and into the uterine cavity. Once properly placed, the IUD is deployed and achieves its active T shape. Each IUD has a different length of time approved for use, with a range of 5–10 years. Fertility is typically restored within a few weeks of IUD removal. IUDs provide highly effective protection against pregnancy, with theoretical and typical user pregnancy rates <1%.

Barrier Methods

Perhaps the best known barrier method is the male condom. The female condom is also a barrier contraceptive method. Female condoms are made out of latex, nitrile, or polyurethane. The female condom is designed to fit into the vagina, with a plastic ring anchoring it in the upper vagina. The condom covers the vaginal walls and extends outside of the vagina where a second ring prevents it from being pressed inward at the time of intercourse. Similar to the male condom, sperm are retained within the female condom after ejaculation, preventing sperm transit from the vagina to the cervix. Clinical studies of consistent use are associated with pregnancy rates of 4%–5%, while typical use pregnancy rates of 21% for the female condom have been reported. Condoms, including both male and female condoms, are highly recommended for use by couples at risk for sexually transmitted infections.

The diaphragm is a round device with a pouch, and the outer edge contains a spring designed to hold the device in place in the upper vagina. The uterine cervix fits into the diaphragm pouch, which is filled with a spermicide by the user prior to insertion. The diaphragm should be inserted before penile penetration and left in place for 1 h after ejaculation. Diaphragms are reusable and come in a variety of sizes. A diaphragm should be fitted by a clinician; the fit should be checked regularly, especially after pregnancy

or significant weight gain/loss. Diaphragms used consistently and correctly have a failure rate of 6%. Typical use failure rates are 20% for the diaphragm.

The cervical cap is a reusable contraceptive device similar to the diaphragm, except that the cap is smaller and fits tightly around the opening to the cervix. Effectiveness is enhanced when used with a spermicide. A cervical cap should be fitted by a clinician and refitted after pregnancy. Failure rates with consistent and typical use are slightly higher than for the diaphragm.

Side effects of barrier methods are minimal. Individuals with allergies to latex should select products that do not contain latex.

Spermicides

Spermicides are detergents that damage the cell membrane of the sperm. Spermicides must be placed within the vagina before penile penetration to be effective. The spermicide most commonly available is nonoxynol-9.

Spermicidal products include foam, creams, gel, vaginal suppositories, and vaginal film. When a spermicide is used as the only method of contraception, the pregnancy rate is 6% in clinical studies but 26% with typical use. Spermicides are often combined with a barrier method, such as a condom or diaphragm.

Spermicides are also impregnated into other contraceptive products to enhance efficacy. The contraceptive sponge is a single-use contraceptive that is inserted into the vagina to cover the uterine cervix. The sponge contains spermicide, which disables or destroys sperm during transit from the vagina to the uterus. The sponge must be inserted prior to intercourse and should be left in place for at least 6 h after intercourse. In women who have never given birth, consistent and correct use of the contraceptive sponge has a failure rate of 1%–9%; typical use failure rates are 11%–24%. Typical failure rates are higher for women who have experienced pregnancy (24%–32%).

Side effects with spermicides are minimal.

Emergency Contraception

Emergency contraception is intended for use after unprotected intercourse, in cases where a contraceptive method was not used or when the primary contraceptive method may have failed.

Two forms of oral emergency contraception, also called morning-after pills, are currently available in the United States. A variety of products, including Plan B[®], contain the progestin levonorgestrel as the active ingredient. Another option is ulipristal acetate, a progesterone receptor modulator, currently marketed as Ella[®]. These progestins prevent pregnancy by preventing the LH surge and, therefore, ovulation. For this reason, emergency contraceptive pills are most effective when taken within 72 h of intercourse. Emergency contraception does not interfere with fertilization or implantation, so these medications are less effective when taken more than 3 days after intercourse. Emergency contraceptives are also less effective in obese women. Levonorgestrel-containing emergency contraceptives reduce the estimated pregnancy rate by 33%. Ulipristal acetate is more effective, reducing the estimated pregnancy rate by 66%. Side effects are similar to those reported for other hormonal contraceptives and include nausea, headache, uterine cramping, unscheduled uterine bleeding, fatigue, and breast tenderness.

The copper IUD is a highly effective emergency contraceptive method. The copper IUD can be inserted up to 5 days following intercourse as an emergency method. Following insertion, the copper IUD will provide continued contraceptive action for up to 10 years unless removed.

Permanent Contraception

Permanent female contraception (also called sterilization) involves obstruction of the oviducts. Surgical tubal ligation is typically performed as a laparoscopic outpatient procedure. During surgery, the oviducts are severed or banded to prevent transit of oocytes or sperm, and major side effects are those of surgery. Nonsurgical methods involve introduction of a device inserter through the cervix, a procedure called a hysteroscopy. During the procedure, the contraceptive device is placed into the opening between each of the oviducts and the uterus. The contraceptive device creates a local inflammatory response and facilitates fibrosis, which blocks the oviduct. Complete blockage of both oviducts can take up to 3 months to be complete, so the woman should use an alternative, effective form of contraception during this period. Reversals of tubal obstruction have been reported. However, tubal obstruction by any method should be considered to be permanent. Female permanent contraception is highly effective, with a pregnancy rate of < 1%.

Removal of the uterus (hysterectomy) for contraceptive purposes is not performed in the United States.

Behavioral Contraceptive Methods

The most utilized nonhormonal contraceptive method is withdrawal or removal of the penis from the vagina prior to ejaculation. While well-controlled clinical trials are lacking, this method is thought to have an overall contraceptive failure rate of approximately 19%.

Periodic abstinence, also known as natural family planning, the rhythm method, or the symptothermal method, is based on the concept that intercourse can result in pregnancy only during a few days in each menstrual cycle. Pregnancy can be avoided by (1) predicting when a woman is fertile and (2) abstaining from intercourse, using a barrier contraceptive or using withdrawal during the fertile period.

The fertile period of each menstrual cycle is defined as the days when intercourse can result in fertilization and formation of an embryo. Sperm travel from the vagina to the oviduct, where fertilization occurs. Sperm can survive in the oviduct for about 5 days, waiting for the oocyte to travel from the ovary after ovulation. The 5 days where intercourse can result in fertilization include the 4 days before ovulation and the day of ovulation.

Predicting the day of ovulation requires regular, consistent, and noninvasive monitoring of the woman's menstrual cycle. Purchased kits can be used to measure urinary LH and determine the day of the LH surge. Progesterone increases basal body temperature, so daily oral temperature measurements can be charted to determine the days of the luteal phase. Cervical mucous is watery during the follicular phase and viscous during the luteal phase. A sample of cervical mucous can be assessed for presence and consistency in order to determine if a woman is in the follicular phase or luteal phase of her menstrual cycle. Menstruation signals the first day of the follicular phase. Charting these changes on a calendar can document if a woman has consistent, regular cycles of similar length. If so, then a prediction of the fertile period can be made for future menstrual cycles, with the fertile period beginning at least 3 days before the expected LH surge and lasting for a total of 5 days. During the fertile period, a woman can choose to avoid intercourse or use an alternative form of contraception to avoid pregnancy.

Few women have such predictable menstrual cycles, contributing to a high pregnancy rate of 25% for this method for contraception. However, periodic abstinence can be used successfully by highly motivated couples to increase time between pregnancies and reduce overall family size.

Summary

There are a variety of contraceptive options currently available for sexually active women. Choices for reversible contraception include highly effective hormonal methods and less effective barrier methods. IUDs and other LARCs provide effective, long-lasting, and reversible pregnancy prevention. Methods that obstruct the oviducts are highly effective and should be considered permanent. When selecting a method, effectiveness and reversibility should be balanced with other considerations, including safety, cost, and side effects.

Nomenclature

AKT	Protein kinase B
AMH	Anti-Müllerian hormone
AR	Androgen receptor
BMP	Bone morphogenetic protein
DES	Diethylstilbestrol
FGF	Fibroblast growth factor
GE	Glandular epithelium
GW	Gestational week
LE	Luminal epithelium
MD	Müllerian duct
MODY5	Maturity-onset diabetes of the young type 5
MRKH	Mayer-Rokitansky-Küster-Hauser
PI3K	Phosphatidylinositol-4,5-bisphosphate 3-kinase
WD	Wolffian duct

Introduction

The female reproductive tract organs form and differentiate during fetal and postnatal stages of development (Kobayashi and Behringer, 2003) (Fig. 1). The oviducts, uterus, cervix and upper portion of the vagina are derived from the paramesonephric ducts or

Fig. 1 Schematic illustration of the female reproductive tract in human and mouse. The female reproductive tracts of human (A) and mouse (B) consist of the ovary, Fallopian tube (oviduct in mouse), uterus, cervix and vagina. A bursal membrane surrounds the ovary in the mouse by not in human.

Fig. 2 Reproductive tract sexual differentiation. The reproductive tract progenitor tissues prior to sexual differentiation are equivalent and contain a fully formed Wolffian duct (blue) and Müllerian duct (red) within the mesenophros (gray). Hormones produced by the fetal testis, anti-Müllerian hormone (AMH), testosterone, and insulin-like 3 (INSL3), activate regression of the MD, differentiation of the WD into the male genital tract (vas deferens, epididymides, and seminal vesicles), and testicular descent, respectively. In females, at this developmental time point the ovary lacks AMH, testosterone, and INSL3. This permits differentiation of the MD into the female reproductive tract (oviducts, uterus and upper vagina), regression of the WD by allowing COUP-TFII signaling and MSX2 expression, and maintenance of the ovaries in an abdominal position, respectively. Modified from Mullen, R.D. and Behringer, R.R. (2014). Molecular Genetics of Müllerian Duct Formation, Regression and Differentiation. *Sex Dev.* 8, 281–296.

Müllerian ducts (MD) and adjacent mesenchyme that form within the fetal kidneys, the mesonephroi (Fig. 2). The MD is an epithelial tube with adjacent mesenchyme cells. The MDs are located adjacent and lateral to the mesonephric ducts or Wolffian ducts (WD) that also reside within the mesonephroi (Fig. 2). The WDs can give rise to male reproductive tract organs, including the seminal vesicles, vasa deferentia and epididymides. In male fetuses, the MDs are eliminated by the action of anti-Müllerian hormone (AMH), whereas the WDs differentiate in response to androgens. However, during female fetal development, the ovaries do not secrete AMH or androgens. Thus, in females the MDs differentiate, whereas the WDs regress (Fig. 2).

Once the MDs have formed, they will become regionalized into the oviduct, uterus, cervix and vagina. Depending on the species, the posterior region of the MDs will fuse to various extents, leading to different uterine morphologies (Kobayashi and Behringer, 2003). At birth, the uterus is composed of a lumen lined by a single layer of epithelial cells with a surrounding undifferentiated mesenchyme. Subsequently, the mesenchyme differentiates into an inner stromal compartment surrounded by inner circular and outer longitudinal smooth muscle layers, the myometrium. The adult uterus contains endometrial glands that produce factors required for uterine receptivity, embryo implantation, embryo survival and development (Gray et al., 2001). Endometrial glands from the luminal epithelium will invade into the uterine stroma in a process called adenogenesis (Spencer et al., 2005). Thus, the development of the fetal and postnatal female reproductive tract organs is complex and essential for the fertility of an individual female.

Formation of the Müllerian Duct

MDs form in amniotes, i.e., birds, reptiles and mammals. Current understandings of MD formation are mostly based on studies in the chicken and mammals. The corresponding developmental stages when MDs form are embryonic day (E) 11.5–13.5 in the mouse, E13.5–16.5 in the rat, Hamburger Hamilton stages 20–30 in the chicken, day 25 of gestation to 2–7 days postpartum in the wallaby and gestational week (GW) 6 to 9.5 (Carnegie Collection stages 16–18) in human (Renfree et al., 1996). Although the timing of MD formation varies between species, the process of how the MD forms is likely similar for each organism.

The formation of the MD can be separated into three phases: initiation, invagination, and elongation (Mullen and Behringer, 2014) (Fig. 3). The initiation phase occurs when a thickened placode-like structure forms on the anterior mesonephric epithelium near the WD. These cells are LHX1 positive and specified by an FGF/LHX1 axis, which, in turn, is regulated by a BMP/PAX2 axis (Atsuta and Takahashi, 2016) (Fig. 3).

The invagination phase occurs when the cells in the placode-like structure become elongated and form apical tight junctions, resulting in a depression of the mesonephric epithelium. Some cells appear to detach from the mesonephric epithelium and move into the space between the mesonephric epithelium and the WD. As the depression becomes deeper, it transforms into

Fig. 3 Müllerian duct formation. (A) MD (red) formation occurs in three phases: initiation, invagination, and elongation. Initiation phase: MD progenitor cells in the mesonephric epithelium (yellow) are specified and begin to express LHX1. Invagination phase: in response to WNT4 signaling from the mesonephric mesenchyme, LHX1 positive (LHX1⁺) MD progenitor cells invaginate posteriorly into the mesonephros towards the WD (blue). Elongation phase: the tip of the MD contacts the WD and elongates caudally in close proximity to the WD requiring WNT9B signaling from the WD. The formation of the MD begins at around E11.5 in the mouse (B) The MD invaginates from the anterior mesonephric epithelium and extends posteriorly guided by the WD. During elongation, mesenchymal cells separate the WD and MD anterior to growing tip. However, at the MD tip, the MD and WD are in physical contact. At around E13.0 the MD crosses over the WD to become located medially. Elongation is complete by E13.5 with the MD reaching the urogenital sinus. E, embryonic day in mouse; D, dorsal; MD: Müllerian duct; P, posterior (caudal); V, ventral; WD, Wolffian duct. Adapted from Kobayashi, A., and Behringer, R.R. (2003). Developmental Genetics of the Female Reproductive Tract in Mammals. *Nature Reviews Genetics* 4, 969–980.

a funnel-like structure. The invagination process is possibly driven by *Wnt4* expressing cells in the mesonephric mesenchyme because *Wnt4* mutant mice have *Lhx1*-specified cells but do not form the MD (Fig. 3).

As the specified MD cells move posteriorly, MD formation enters the elongation phase. The posterior tip cells of the MD, which have shown to be *Wnt4* positive, will invade through the common basal lamina between the mesonephric epithelium and the lateral side of the WD (Prunskaitė-Hyryläinen et al., 2016). Following the tip cells, the rest of the MD cells will move along the WD in an anterior to posterior manner. When the MD elongates past the middle of the WD (posterior to the gonad), the MD will elongate dorsomedially across the WD, but will remain in close contact with it. After reaching the medial side of the WD, the MD resumes its anterior-posterior elongation along the medial side of the WD. At the end of the elongation phase, the MD tip reaches the urogenital sinus and fuses (Fig. 3).

Although the cellular mechanisms of MD formation are not fully understood, recent studies have shown that both cell proliferation and migration are involved in MD elongation. Studies in both chicken and mouse have shown that the MD cells are proliferative along the entire anterior to posterior length. In addition, cell migration may play an important role during the elongation process. The tip cells extend prominent processes, suggesting that the tips cells are actively investigating their environment for MD elongation (Huang et al., 2014). PI3K/AKT activity has been shown to be required for MD cell migration and elongation in rat embryos (Mullen and Behringer, 2014). It is also possible that cell shape changes may also contribute to MD elongation.

The relatively rapid elongation of the MD during mouse development has led to speculation that cells may be contributed from neighboring tissues, such as the adjacent WD, the mesonephric mesenchyme or the mesonephric epithelium. However, recent studies show that cell contributions from neighboring tissues are not found in both chicken and mouse (Mullen and Behringer, 2014). Therefore, cell recruitment is not a major cellular mechanism that contributes to the elongation of the MD.

The MD elongates in a unique manner, i.e., tube-dependent tubulogenesis. In 1937, Grünwald found that the MD elongation is dependent on the presence of the WD (Grünwald, 1937). It was found that the *Wnt9b* mutant mouse lacked MD formation. *Wnt9b*

is expressed in the WD. Thus, WNT9B secreted from the WD is required for MD elongation, providing a molecular explanation why MD elongation is dependent upon the WD (Mullen and Behringer, 2014).

Interestingly, MD cell differentiation switches between mesenchymal and epithelial states during MD formation. In the initiation phase, the specified MD cells are considered “mesoepithelial” and invade into the mesonephric mesenchyme. The MD cells are histologically epithelial but express mesenchymal molecular markers (Mullen and Behringer, 2014). After MD elongation is completed, the MD cells in female fetuses down-regulate mesenchyme markers and up-regulate epithelial molecular markers.

Wolffian Duct Regression

In amniotes, the initial formation of the reproductive tracts of genetic male and female embryos is identical with two pairs of simple epithelial tubes, the WD and MD, surrounded by mesenchymal cells. However for proper sexual differentiation, only one of these pairs of tubes will differentiate while the other is eliminated. As discussed above, this is regulated by the presence or absence of fetal gonadal hormones. The fetal male gonad secretes androgens, causing the WD to differentiate into the mature male reproductive tract organs. In females, it is necessary to eliminate or regress the WD. The absence of androgens in female fetuses leads to the elimination or regression of the WD. In female rodents, without androgens, degeneration of the WD is observed beginning midway between the gonads and point of contact with the urogenital sinus and proceeds cranial (head) to caudal (tail). Lower, caudal segments of the WD remain and fuse with the MD and urogenital sinus to form the lower portion of the vagina (Fig. 2). The ability of androgens (from the testis) to block WD regression in females has been shown in tammar wallaby. Grafting of a testis in female tammar pouch young resulted in a block of WD regression and differentiation of the WD. Similarly, mutations in the *androgen receptor* (AR) gene in humans and rodents result in intersex phenotypes and genetically male (XY) individuals lack WD-derived tissues. Further, observations in rodent models indicate androgen signaling in the WD mesenchyme may allow cell survival and differentiation of the adjacent WD epithelial tube and lack of androgen signaling in the mesenchyme results in cell death, thus facilitating WD regression (Shaw and Renfree, 2014).

Early studies of female reproductive tract differentiation during WD regression were limited to two-dimensional analyses in animal models. Recently, light-sheet microscopy has made it possible to quickly generate high-resolution three-dimensional images of fluorescently-labeled fetal organs. Light-sheet microscopy was used to visualize the developing human female reproductive tract at GW 10.5, 11.5 and 13 weeks. The human embryos were immuno-fluorescently stained with PAX2 antibody (which binds WD and MD epithelial cells) and imaged. At GW 10.5 fusion of the MD to form the uterovaginal canal was observed in female embryos. The WD was still intact however there was initial regression of the mesonephric tubules. At GW 11.5 WD regression was apparent and the MDs had grown in length. By GW 13, the WD was fragmented and completely regressed distally (Belle et al., 2017).

WD regression has long been considered a passive process, where lack of androgens in female fetuses fails to support the differentiation of the WD. However, several recent studies suggest that WD regression requires active signaling to promote cell death of the epithelium. MSX2, a transcription factor expressed in the WD epithelium, and orphan nuclear receptor chicken ovalbumin upstream promoter transcription factor II (COUP-TFII) found in the WD mesenchyme have both been identified as potential mediators of WD regression in female reproductive tract differentiation. Down-regulation of *Msx2* expression in the WD epithelium either in response to diethylstilbestrol (DES) exposure or in a *Msx2* mutant mouse model in females results in persistent WD remnants dorsal to the vagina and reduced apoptosis (programmed cell death) in the WD epithelium (Yin et al., 2006). COUP-TFII, a mesenchyme specific transcriptional regulator, is required for WD regression during differentiation of the female reproductive tract in the mouse. Loss of the *Coup-tfII* gene in the WD mesenchyme results in retention of the WD independent of androgen signaling. In fetal males, androgens secreted from the testis presumably antagonize COUP-TFII function and prevent WD regression (Zhao et al., 2017).

Oviduct Development

The oviduct, or Fallopian tube in women, is a paired organ that is essential for fertility. In mature animals, the oviduct is the conduit for oocyte and embryo transfer to the uterus and is the site of fertilization. The ovulated oocyte enters the oviduct through the infundibulum, which is the most anterior region of the oviduct, and travels through the ampulla, which contains numerous longitudinal epithelial folds and abundant cilia to aid in oocyte transport. Upon fertilization, the zygote will travel through the isthmus region of the oviduct. The isthmus has fewer epithelial folds and cilia than the ampulla, but thicker smooth muscle layers. To leave the oviduct, the zygote must travel through the uterotubal junction to enter into the uterine horn/body. This junction is an ovarian hormone-controlled valve that controls the movement of spermatozoa/zygotes between the oviduct and uterus.

Defects in oviduct formation or the formation of occlusions can cause infertility. This may be overcome via superovulation, in vitro fertilization and embryo transfer into the uterus, but these are costly methods with demanding hormonal regimens and relatively low success rates. Tubal occlusions are caused most frequently by infections, but structural abnormalities arising during peri-natal development can have the same result. Very little is known of how and what regulates oviduct development.

The study of Fallopian tube development in women is limited, requiring the use of other animal models including both mammals and birds. However, there are some striking differences in the gross morphology and histology of various species. Oviduct coiling is observed in some species (e.g., mice), but not others (e.g., women, sheep, chickens). A bursa surrounds the oviduct and

ovary (e.g., mice) in certain species, which is absent in others (e.g., women). Oviduct epithelial folding, particularly in the ampulla region can be minimal (e.g., mice) or very extensive (e.g., women, sheep). Despite these differences, the oviducts function in a very similar manner.

Mammalian female reproductive organs, including the oviduct, uterus, cervix, and anterior vagina, are all derived along the anterior-posterior axis of the MD during embryonic development. The most anterior aspect of the MD gives rise to the oviduct. The developing MD forms a shepherd's crook shape around the ovary. The end of the curved portion of the "crook," posterior to the ovary, is referred to as the *flexura medialis* and is proposed to define the border between the region of the MD that will become the oviduct and that of the uterus (Agduhr, 1927).

The TGF β , WNT and mTOR signaling pathways have been identified as potential regulators of oviduct development. TGF β may play a key role in controlling cell proliferation, differentiation and apoptosis during oviduct development (Conery et al., 2004; Elliott and Blobe, 2005; Li et al., 2011; Rodriguez et al., 2016). Regulation of TGF β signaling during oviduct development likely involves extracellular matrix proteins, including matrix metalloproteinases and tissue inhibitors of metalloproteinases (ex. MMP-2, -9, TIMP-2) which act via enzymatic cleavage and activation or repression of signal transducers (Hu et al., 2004; Imai et al., 1997; Lesniak-Walentyń and Hrabia, 2016).

In addition to TGF β signaling, the WNT pathway appears to play a direct role in oviduct development. Oviduct development and formation is regulated tightly by correct expression of canonical WNT signaling pathway members in both the epithelia (*Wnt7a*) and mesenchyme (*Wnt4*, *Wnt5a*, *Ctnnb1*). WNT signaling during oviduct development is associated with the appearance of coiling and initial formation of the anterior region of the MD, suggesting that this pathway plays a key role in anterior-posterior oviduct extension and differentiation.

mTOR signaling appears to play a key role in smooth muscle differentiation and function in the oviduct. mTOR signaling is downstream of PI3K/AKT signaling and regulates cell growth and proliferation in response to growth factors and nutrients and is negatively regulated by a heterodimeric complex of TSC1 and TSC2. In the mouse, conditional deletion of *Tsc1* in both the MD mesenchyme and in all MD cell types results in infertility related to oviduct hyperplasia and formation of occlusions and hydrosalpinx in the ampulla (Daikoku et al., 2013; Tanaka et al., 2012). Conditional deletion of *Tsc2* in the MD mesenchyme resulted in infertility that may be related to the formation of oviductal blockages, but oviductal histology was not reported. The uterine phenotype was characterized by the presence of myometrial hyperplasia (Kaneko-Tarui et al., 2014). It is possible that this also occurred in the oviductal smooth muscle layers, which would adversely affect oocyte/zygote transport, resulting in a phenotype similar to oviduct blockage.

Uterine Development

In eutherian mammals, the majority of the development and differentiation of the female reproductive tract is completed by birth. However, the uterus is not fully developed or differentiated by birth and the histoarchitecture of this organ is established postnatally. Postnatal radial patterning morphogenesis establishes two functional compartments, the endometrium and the myometrium, surrounded by the perimetrium. The endometrium consists of two epithelial cell types, luminal epithelium (LE) and glandular epithelium (GE), and two stratified stromal compartments including a densely organized stromal zone, blood vessels and immune cells. The myometrium includes the smooth muscle layers of the uterine wall, an inner circular layer and an outer longitudinal layer (Gray et al., 2001). Morphogenic events common to morphogenesis of the uterus include: (1) organization and stratification of the endometrial stroma, (2) differentiation and growth of the myometrium and (3) coordinated development of the endometrial glands. The LE will invaginate into the stroma to generate the GE (endometrial or uterine glands), resulting in an extensive network of glands that extends towards the myometrium (Gray et al., 2001; Spencer et al., 2005).

Humans have a simplex uterus that consists of a single uterine body. The endometrium is lined by a LE that contains glands that radiate from the surface to the endometrial-myometrial interface. The endometrium is divided into two functional layers, the upper *stratum functionalis* (containing glands and is surrounded by loose stroma) and the lower *stratum basalis* (containing branched glands and dense stroma). During menses, the endometrial *stratum functionalis* is shed. The *stratum basalis* includes a zone that contains loose stroma and endometrial glands and another zone where endometrial glands terminate and endometrial progenitor and stem cells are thought to reside (Spencer et al., 2005).

During pregnancy, uterine glands secrete histotroph that is essential for endometrial receptivity of the embryo, conceptus survival, implantation, development and growth in sheep, cattle, pigs, horses and rodents (Gray et al., 2001). Histotroph is present in the uterine luminal fluid and is a complex, undefined mixture of ions, amino acids, carbohydrates, proteins, lipids, and other substances that are selectively transported into the uterine lumen by the epithelium, as well as specific secretory products encoded by genes and expressed in the LE and GE. Evidence shown in mouse and sheep suggests that uterine glands are required for female fertility, with defects resulting in abnormal implantation and early pregnancy loss (Filant and Spencer, 2014; Spencer et al., 2005).

Knowledge of prenatal uterine development is most complete in rodents. However, the basic biology of this process is assumed to be similar across mammalian species and the morphogenesis of the postnatal uterus is dependent on the maturity of the uterus at birth (e.g., gestational length) and perhaps the interval between birth and puberty (Gray et al., 2001). For example, in rodents, at birth, the uterus has not yet differentiated into endometrial stroma and myometrium, whereas in certain domestic animals and humans, the endometrial stroma and myometrium are present at birth (Spencer et al., 2005).

Fig. 4 Schematic illustration of endometrial adenogenesis in the mouse uterus. The uterus consists of two epithelial cell types (purple), the luminal epithelium (LE) and glandular epithelium (GE). The myometrium is composed of two smooth muscle layers: the inner circular layer (pink) and outer longitudinal layer (dark red). Stages of adenogenesis are indicated. GE, glandular epithelium; LE, luminal epithelium.

Uterine adenogenesis is the process of endometrial gland formation from the LE. It includes epithelial budding, extension and penetration into the stroma with coiling and branching. In humans, rodents and livestock, this process is completed postnatally (Gray et al., 2001). In mice, at birth, the uterus is comprised of a simple epithelium surrounded by undifferentiated mesenchyme with no endometrial glands. At Postnatal Day (P) 5, three mesenchymal layers are radially oriented and segregated into the endometrial stroma and inner circular and prospective outer longitudinal myometrial layers and the formation of epithelial buds by epithelial invaginations. Between P9 to P15, simple tubular glands develop that are not tightly coiled or branched (Fig. 4). By P10, the outer longitudinal layer of the myometrium becomes organized into bundles. At P15, the adult configuration of the mouse uterus is already established and as females mature, the glands lengthen as the uterus grows (Gray et al., 2001). P21 marks the end of the postnatal stage of gland formation. Many of these studies were performed using two-dimensional histological analyses. Recently, the three-dimensional morphology and organization of adult uterine glands has been examined (Arora et al., 2016).

Knowledge of prenatal and postnatal female reproductive tract development in humans is limited. By GW 12, the uterine corpus and cervix is has formed and the LE invaginates to give rise to epithelial buds. By GW 20–22, the myometrium is well defined but endometrial gland development has not progressed beyond epithelial buds. At birth, the uterine histoarchitecture is similar to that of an adult, but less developed. From birth to the onset of puberty, the glands develop slowly. A female at 6 years of age will have endometrial glands that will extend from one-third to one-half of the distance of the stroma to the myometrium. The mature uterine histoarchitecture is observed at puberty with glands extending to the inner circular layer of the myometrium. Endometrial gland formation in humans (fetus and neonate) involves differentiation of the GE from the LE, followed by radial development of the tubular glands through the endometrial stroma extending to the myometrium.

Multiple studies have established that prenatal urogenital tract development in female mammals is an ovary (hormonal) independent process (Gray et al., 2001). These studies have shown that uterine development and endometrial adenogenesis can proceed in the absence of the ovary for varying periods of time during early postnatal development. In rats, circulating estrogens increase between P9 and P11 in association with gland remodeling, but early postnatal uterine development and adenogenesis are both ovary- and adrenal-independent (Gray et al., 2001; Spencer et al., 2005). In mice, the introduction of hormones during a critical postnatal window causes a delay in gland formation or the loss of glands (Filant and Spencer, 2014).

Gland morphogenesis is highly complex and mediated by diverse mechanisms (hormonal, cellular and molecular). Despite being studied for decades, very little details are available, compared with other epitheliomesenchymal organs. The communication between the epithelium and stroma appears to be mediated by *Wnt* and *Hox* genes, intrinsic growth factors systems and the extracellular matrix (Spencer et al., 2005). In recent years, knockout (*Hoxa10*, *Hoxa11*, *Lef1*, *Wnt4*, *Wnt5a*) and conditional knockout (*Ctnnb1*, *Foxa2*, *Wnt7a*) mutants mouse models have been used to identify genes involved in uterine gland development (Filant and Spencer, 2014). Although some cellular events and molecular pathways have been identified through gene expression and mouse models, there is still a significant gap in knowledge of how glands develop and their morphogenesis.

Malformations of the Uterus

Uterine malformations can be classified into three main groups, (1) formation defects, (2) fusion defects, and (3) septal absorption defects (Jacquinet et al., 2016). The actual prevalence of uterine malformations has been difficult to evaluate because some defects may be considered normal variants of uterine anatomy, for example, arcuate uterus. Chan et al. (2011) reported a 5.5% prevalence of uterine malformations in an unselected population, 8.0% in infertile women, 13.3% in women with a history of miscarriage, and 24.5% in patients with a history of miscarriage and infertility. This lead to the conclusion that women who are infertile and/or have had spontaneous abortions are more likely to have a uterine malformation (Chan et al., 2011).

Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome or Müllerian agenesis is characterized by the absence of the uterus, cervix and upper portion of the vagina in a 46,XX female; it is the second most common cause of primary amenorrhea (Fontana et al., 2017). It is divided into two main subtypes: (1) MRKH type 1 in which only the female reproductive tract is affected and (2) MRKH type 2 which can manifest with malformations of other organs systems such as: renal, skeletal (spine and limb) and less frequently auditory and heart defects. Even though MRKH is most severe in the spectrum of uterine defects, its incidence is relatively low, with only 1 in every 4500–5000 newborn females being affected. However, the association of MRKH type 2 with other organ system defects suggests that abnormal MD development involves the disruption of developmental pathways important for structures derived from the intermediate mesoderm of the embryo (Fontana et al., 2017).

The cause of uterine malformations is thought to be multifactorial and in the case of MRKH, the mode of transmission is thought to be autosomal dominant with incomplete penetrance and variable expressivity. First-degree relatives of patients presenting with a uterine anomaly are said to have a 1%–5% recurrence risk. There are reports of familial cases suggesting a predisposing genetic background. Conversely, there have been studies of monozygotic twins that show discordant phenotypes: MRKH vs. normal uterine anatomy, suggesting nongenetic mechanisms that point towards epigenetic and/or environmental factors (Jacquinet et al., 2016).

Relatively little is known about the genetic pathways that regulate the development of the female reproductive tract and lead to uterine malformations in humans. However mutation or deletion of certain genes have been found to be associated with reproductive tract defects in humans including: *EMX2*, *HNF1 β* , *LHX1*, *PBX1*, *WNT4*, *WNT7A*, and *WNT9B*. In patients with MRKH syndrome, a rare pathogenic deletion in region 17q12 containing *LHX1*, as well as *HNF1 β* , has been found to be statistically significant compared to a control population (Jacquinet et al., 2016). Mutations in *HNF1 β* are the cause of a form of maturity-onset diabetes of the young type 5 (MODY5). MODY5 clinically manifests with diabetes, renal disease and genital malformations (MRKH syndrome). Mutations in *HNF1 β* have only been found in patients with both renal and uterine malformations, and are rare in cases of isolated uterine defects (Fontana et al., 2017). Recently, in a case control study of 517 Chinese women with incomplete Müllerian fusion, a novel nonsense mutation in the *EMX2* gene (p.E142X) was detected in one patient (0.19%). The authors report functional studies in cultured cells, suggesting a dominant negative effect of the mutation (Jacquinet et al., 2016). Even though this mutation is uncommon in the studied population, *EMX2* is the first gene to be identified suggestive of a cause for an isolated uterine malformation (Jacquinet et al., 2016). An association study performed in a Chinese Han female population with MRKH found two susceptibility SNPs (single nucleotide polymorphism) in *WNT9B* and *PBX1* associated with MRKH syndrome risk (Ma et al., 2015). In humans, *WNT4* was the first gene to be associated with uterine defects accompanied by hyperandrogenism (Fontana et al., 2017). *WNT4* mutations are more commonly associated to an MRKH-like syndrome because of the concomitant virilization. *WNT7A* mutations have been linked to Al-Awadi/Raas-Rothschild and Fuhrmann syndromes which are characterized by skeletal dysplasia, hypoplastic pelvis and females may present with an absent uterus (Jacquinet et al., 2016).

Prenatal exposure of fetuses to endocrine disruptors can affect the development of the uterus in mice and humans. Diethylstilbestrol (DES) is a synthetic estrogen that was used from 1938 to 1971 to prevent miscarriages in millions of pregnant women. However, it was later discovered that prenatal and perinatal exposure to DES disturbs the development of the reproductive tract in both humans (males and females) and mice (Spencer et al., 2005). Prenatal exposure of human fetuses to DES alters the organizational program of the female reproductive tract tissues and disrupts the normal expression or function of genes in an epigenetic manner. These induced abnormalities have set the stage for infertility, cervicovaginal cancer and other complications in exposed females and their offspring in a transgenerational manner.

Glossary

Chemokines A family of small cytokines or signaling proteins secreted by cells. Their name is derived from their ability to induce directed chemotaxis in nearby responsive cells.

Cryptic female choice A form of mate choice which occurs both in pre- and postcopulatory circumstances when females in certain species use physical or chemical mechanisms to influence a male's reproductive success.

Glycome Strictly speaking this is the entire complement of sugars, whether free or present in more complex molecules, of an organism. In the context of this article it refers specifically to the sugars present on the outer surfaces of the cell.

microRNA A microRNA (abbreviated miRNA) is a small noncoding RNA molecule (containing about 22 nucleotides) found in plants, animals, and some viruses, that functions in RNA silencing and posttranscriptional regulation of gene expression.

Polyspermy Polyspermy occurs when two or more spermatozoa enter the cytoplasm of a single oocyte. In mammals this usually leads to abnormal fertilization and embryonic death, but in some other taxonomic groups (e.g., amphibians) it is perfectly normal.

Sperm competition This is the competitive process that results when spermatozoa from two or more different males strive to fertilize the same cohort of egg(s) during sexual reproduction.

Utero-tubal junction A narrow and tortuous region of the female reproductive tract that links the uterus to the oviduct.

Introduction

Why do most vertebrates produce and ejaculate far more spermatozoa than the numbers they actually need for fertilization? For species with external fertilization (many fishes and amphibians) a simple answer is that when spermatozoa are delivered into the watery environment near to the egg most will be lost and only a minority will find their way towards the egg. The situation for species with internal fertilization is different. With a few exceptions such as the Viscacha (*Lagostomus maximus*), a South American rodent that ovulates about 900 eggs at once (Weir, 1971), females of internally fertilizing species usually ovulate small numbers of eggs, and it seems logical that they should only need similarly small sperm numbers to assure fertilization success. However, it is clear that the logical scenario is wildly unrealistic because males produce billions of spermatozoa every day. In the early 1970s Parker (1970) proposed that because females frequently accept matings by more than one male, rivalry between males, and between their ejaculates would lead to "sperm competition." In this scenario, ability to produce and ejaculate larger numbers of spermatozoa than competing males represents an advantage in terms of breeding success. A detailed review of the massive body of research into sperm competition and "cryptic female choice," a complementary mechanism whereby the females exhibit a high degree of postcopulatory sperm selection, is beyond the scope of this article (for reviews, see Birkhead, 1998; Orr and Zuk, 2014). Nevertheless, cryptic female choice (between males) is a reproductive mechanism that somehow involves the assessment of sperm quality, including their genetic complement, thereby favoring some males at the expense of others. As such it represents a powerful influence in terms of sexual selection and evolution. However, it is increasingly clear that the female reproductive tract distinguishes between the individual spermatozoa within a single ejaculate. Recent studies have shown that there are numerous molecular differences between individual spermatozoa, which are able to bias the genetic outcomes of mating and fertilization. Sperm transport and selection are therefore now seen as highly complex and sophisticated mechanisms in which every anatomical region of the female reproductive tract has a distinct role. The subtlety underlying this statement is well illustrated in a conclusion reached by Rodriguez-Martinez et al. (2016) in a study of hyaluronan function, where its role within the deep folds and crevices of the oviduct is not necessarily the same as its role within the lumen:

Both hyaluronan and its CD44 receptor are particularly evident in the deep mucosal furrows of the sperm reservoir, in which most spermatozoa are embedded in; kept alive, uncapacitated but also undetected by the immune system of the female.

Sperm Transport in Mammals

After copulation, spermatozoa in the mammalian ejaculate make their way through the female reproductive tract and eventually reach the vicinity of the ovulated eggs within the oviduct. This journey, known generally as "sperm transport," involves several physiological processes acting in concert. Ejaculation itself forces spermatozoa to interact directly with the mucus produced by

the cervix. In many species, including humans (Yudin et al., 1989), cervical mucus consists of a fine network of microscopic fibers and the spermatozoa have to penetrate and pass through this mesh-like network powered by their own motility in order to reach the uterus. Thus the cervical mucus represents an initial selective barrier for spermatozoa, and many with inadequate motility cannot make any further progress. Transport of those spermatozoa that reach the uterus is assisted by muscle contractions, pushing the spermatozoa towards the next major barrier; the utero-tubal junction (UTJ). This is a narrow and tortuous, mucus-filled, tubular structure that controls access to the oviducts (also known as the Fallopian tubes) and, in fact, prevents the entry of most spermatozoa. It is now known that the UTJ is another important barrier, blocking the progress of many spermatozoa towards the oocyte and ensuring that only a small and privileged subpopulation of spermatozoa are ever allowed even to approach oocytes. Understanding sperm transport, and especially the key factors which distinguish the “privileged” sperm subpopulation from all the others, is extremely important in many different aspects of reproductive biology. From an evolutionary or genetic viewpoint we might ask whether the female reproductive tract is only permitting the progress of spermatozoa that fulfill specific criteria? It is known, for example, that mate choice in species from fishes to humans is driven, among other factors, by efforts to match male and female genetic criteria such as the major histocompatibility complex (MHC) (Burger et al., 2017; Wedekind and Furi, 1997; Wintemitz et al., 2017; Ziegler et al., 2002) and it is likely that similar processes are involved in postcopulatory sperm selection.

The development of artificial insemination (AI) technology between the 1950s and 1980s led to some extensive studies of sperm transport within the female reproductive tract being undertaken in cattle, pigs, and sheep. These studies typically involved the experimental insemination of oestrous females with known doses of semen; the females were slaughtered at intervals after insemination, the reproductive tracts flushed, and the different anatomical regions examined for the presence of spermatozoa. Data from studies in cattle and sheep revealed that only about 1%–3% of the total number of uterine spermatozoa reached the site of fertilization, while in pigs the reduction in sperm numbers was much greater (less than one thousandth of the inseminated population) (First et al., 1968). Interestingly First et al. (1968) estimated that 83,000 spermatozoa had reached the oviducts after about 4 h, and that this value remained constant over the ensuing 24 h period. This figure is surprisingly close to the mean of 79,055 spermatozoa detected by Mburu et al. (1996) when preovulatory inseminations were performed. In this study the majority of the oviductal spermatozoa (75,293; >96% of the total) were located at the UTJ, and the remaining 4% of spermatozoa (3132) were situated within the oviductal isthmus. The oviductal isthmus represents the initial anatomical region of the oviduct and is characterized by a narrow lumen lined by columnar epithelial cells.

The results obtained in agricultural species agreed with observations that hamster and rabbit spermatozoa accumulate in the oviductal isthmus 1 or 2 h after mating (Overstreet and Cooper, 1975; Yanagimachi and Chang, 1963), and remain there until the onset of ovulation. Direct video imaging of sperm behavior within the oviducts (Demott and Suarez, 1992; Kölle et al., 2010; Suarez, 1987) confirmed many of these observations and led to the recognition that the oviductal isthmus functions as a specialized storage reservoir, in which the spermatozoa are able to survive for varying durations prior to ovulation. Observations of spermatozoa taken from the isthmus reservoir of several species have consistently shown that their motility is suppressed (see, for example, Burkman et al., 1984; Overstreet and Cooper, 1975) and motility suppression has also been observed in spermatozoa exposed to oviductal fluid.

When a suspension of mammalian spermatozoa is placed on a slide and viewed under the microscope, the cells appear to move in random directions. However, it is important to recognize that this type of movement is not representative of the situation pertaining within the reproductive tract. There is convincing evidence that sperm behavior is markedly influenced by the physical and chemical characteristics of their local environment. Ovulation stimulates alterations to the way that fluids flow within the female reproductive tract, and it has recently been shown that spermatozoa sense these changes and use them to navigate their way towards the oocytes (Miki and Clapham, 2013). This is not, however, the only sperm guidance system in operation; it is now known that capacitated spermatozoa are sensitive to minute concentration gradients of chemoattractants within the oviduct and use these for chemotactic guidance in their progress towards the oocytes (Bian et al., 2012; Guidobaldi et al., 2012; Perez-Cerezales et al., 2015). Temperature gradients are also known to exist within the oviduct (Hunter, 2012) and it has been proposed that spermatozoa therefore can also employ thermotaxis for guidance towards the oocytes.

Investigations of chemotactic mechanisms that guide spermatozoa towards the oocyte(s) have identified progesterone as a significant molecular signal that modifies sperm flagellar activity (Armon and Eisenbach, 2011; Blengini et al., 2011; Guidobaldi et al., 2012; Oren-Benaroya et al., 2008; Teves et al., 2009). The action of progesterone is elicited via its receptor, Catsper (Arnoult et al., 2011; Lishko et al., 2011; Strunker et al., 2011), and the consequent modulation of intracellular calcium concentrations that change flagellar activity (Kaupp et al., 2008). Two recent studies (Caballero-Campo et al., 2014; Zuccarello et al., 2011) have demonstrated that sperm chemotaxis is not only modulated by progesterone but also via chemokine-receptor interactions involving factors produced by oocytes, granulosa cells, and endometrial cells. One of the studies (Zuccarello et al., 2011) focused on the interaction between CXCR4 (chemokine CXC motif receptor 4) present in human spermatozoa and SDF1 (chemokine stromal cell-derived factor-1), a member of the CXC chemokine family also known as CXCL12. It is of specific interest here that <30% of live human spermatozoa express CXCR4 (Kim et al., 1999; Zuccarello et al., 2011), meaning that approximately 70% of spermatozoa would be unresponsive to chemical signals emanating from granulosa cells and oocytes. Caballero-Campo et al. (2014), who identified CCR6, a chemokine receptor common to several chemoattractant peptides (Yang et al., 1999), in human and mouse spermatozoa, noted that CCR6 expression on the sperm surface was more intense after capacitation and also noted that the protein was not detected in every cell. That chemotaxis is stimulated by several different mechanisms is something of a puzzle: do the separate mechanisms operate synergistically or do they perhaps indicate the existence of an exceedingly sensitive and discriminatory sperm selection system?

What Are the Mechanisms Behind Sperm Storage in the Female Reproductive Tract?

Although the duration of sperm storage in mammals is usually measured in hours, in some mammals such as the dog (England et al., 2006) the storage period may last several days. This reflects the unusual situation in canids whereby the oocytes are ovulated as primary oocytes. These canine oocytes are not capable of being fertilized until about 60 h after ovulation; this explains why the presence of capacitated spermatozoa near oocytes is not required until some hours after ovulation. It is also worth noting that a number of bat species have the ability to store spermatozoa in the female reproductive tract for several months (for review, see Holt and Fazeli, 2016). Although not the focus of this article, it is worth noting that many species, especially the nonmammalian vertebrates such as birds and reptiles, store spermatozoa within the female tract for weeks, months, or even years. This adaptation enables them to mate and receive spermatozoa, but then to delay the processes involved in ovulation and embryo development until a more opportune time.

The mechanisms responsible for prolonging sperm survival in the female reproductive tract involve interactions between the sperm heads and the surface of the oviductal epithelium. Experimentally, coculture of spermatozoa with oviductal epithelial cells (OEC) has repeatedly been shown to prolong sperm viability across a variety of mammalian species (Dubuc and Sirard, 1995; Ellington et al., 1998; Sidhu et al., 1998; Thomas et al., 1995; Yeung et al., 1994). The formation of intimate associations between spermatozoa and the oviductal epithelial surface suggests that direct membrane–membrane contact is important. In fact, if direct contact is prevented, the beneficial effects of coculture are also prevented (Yeste et al., 2009). Intermembrane contact stimulates mutual cell signaling dialogues between the spermatozoa and oviductal epithelial cells, with resultant effects on the activity of both cell types. Murine and porcine oviductal epithelial cells are known to respond to the presence of spermatozoa in vivo by modulating gene transcription and protein synthesis (Fazeli et al., 2004; Yeste et al., 2014), while (boar) spermatozoa respond to the presence of oviductal proteins with reduced motility and an accelerated increase in intracellular pH (Satake et al., 2006).

The observation that exposure to oviductal proteins causes an increase in intracellular pH is of interest because it is not correlated with increases in capacitation and the acrosome reaction, both of which are processes that precede sperm–egg interactions and facilitate fertilization (Gadella and Luna, 2014). In fact, the oviductal proteins inhibit the completion of these processes and maintain the spermatozoa in a quiescent and stable state, while simultaneously preparing them for fertilization as soon as conditions are appropriate (Maillo et al., 2016; Rodriguez-Martinez et al., 2016) (see Fig. 1).

Several investigations of prolonged sperm survival have shown that membrane fractions and protein extracts isolated from OEC can support sperm viability in vitro. Efforts to identify a subset of OEC membrane proteins that bound specifically to the surface of boar spermatozoa demonstrated the presence, among others, of a group of heat shock proteins (Hsp70 kDa 1A, Hsp90, Hspa8 (formerly known as Hsc70) and glucose regulated protein 78 (GRP78)) (Lachance et al., 2007). Other studies that focused on bovine sperm–OEC interactions also identified GRP78 and Hsp60 for their sperm binding ability (Boilard et al., 2004). Subsequent experiments on in vitro sperm survival in the presence of recombinant Hspa8 showed convincingly that this protein could extend the lifespan of boar, bull, and ram spermatozoa under culture conditions and even when added to sperm extenders (Elliott et al., 2009; Lloyd et al., 2008, 2009). Hspa8 has been shown to exert its effects immediately upon contact with the sperm plasma membrane by increasing membrane fluidity as measured by fluorescent recovery and photobleaching (Moein-Vaziri et al., 2014). In this study the membrane fluidization and protective effects were shown to be (a) dependent on the presence of sperm plasma membrane cholesterol, (b) to be reduced by incubation in a capacitating environment, and (c) to be reversibly restored

Fig. 1 Diagram summarizing the main events that occur during oviductal sperm storage in pigs, cattle, and sheep. (A) Spermatozoa enter the oviduct isthmus via the utero-tubal junction. (B) Some spermatozoa bind to oviductal epithelial cells (OEC) surfaces, whereupon their motility and intracellular calcium concentrations are reduced; capacitation is also inhibited. (C) The direct contact between spermatozoa and epithelial cells induces de novo gene expression and protein synthesis. Multiple proteins, including heat shock proteins, are secreted into the oviductal lumen where they protect sperm membranes and facilitate sperm storage. (D) Increased periovulatory progesterone production induces spermatozoa to escape and resume their progress towards the oocyte(s). Reproduced with permission from Holt, W. V. and Fazeli, A. (2016). *Annual Review of Animal Biosciences* 4, 291–310.

by depleting and then replenishing membrane cholesterol through incubating spermatozoa with cholesterol-loaded cyclodextrins. In addition, sperm exposure to hspA8 induced a decrease in mitochondrial activity. The heat shock proteins are multifunctional molecules that occur in multiple taxonomic groups and species, including bacteria, plants, and higher vertebrates (Liao and Tang, 2014; Liu et al., 2012). Moreover, HspA8 is an exceptionally well conserved member of the Hsp70 family.

What Governs Sperm Selection in the Female Reproductive Tract?

What cues are available to the female reproductive tract that enable sperm selection? These probably include responses to external signaling molecules, the presence of sperm surface markers such as ubiquitin (Sutovsky et al., 2001), and the complex arrays of carbohydrates that constitute the “glycome” (Kadirvel et al., 2012; Kuo et al., 2009; Pang et al., 2009; Silva et al., 2014). In addition, there is emerging evidence that each individual spermatozoon contains its own population of microRNAs (Curry et al., 2011; Das et al., 2013; Salas-Huetos et al., 2014). These are RNA sequences of about 20 bases (Hausser and Zavolan, 2014), which are known to be powerful modulators of gene expression. As the various microRNA species adopt unique three-dimensional shapes they are important candidates in any mechanism that involves selection. Little information is currently available about their role in sperm selection *in vivo*, but evidence from clinical studies supports the hypothesis that microRNAs can make the difference between successful and unsuccessful infertility treatment (Garcia-Herrero et al., 2011; Garrido et al., 2009, 2013). Correlations between the fertility of artificially inseminated bull semen and the nature of its microRNA content have also been demonstrated (Kasimanickam et al., 2012).

As mentioned above, the cervix and UTJ present spermatozoa with physical, chemical, and anatomical barriers that control their progress (Martyn et al., 2014; Yaniz et al., 2014). Blind-ended cervical crypts can block sperm transport, but may also allow live spermatozoa to be stored for several days before continuing. Because the physical nature of cervical mucus is under hormonal control during the reproductive cycle, it can both facilitate and inhibit sperm transport towards the uterus and oviduct. In human clinical medicine the “post-coital” test has been widely used to test for pathological incompatibility between spermatozoa and mucus (Barratt et al., 1992), which can be a cause of infertility.

Paradoxically, if the female reproductive tract allowed too many spermatozoa to reach the oviduct there would be a heightened risk of polyspermy (where individual oocytes are simultaneously penetrated by two or more spermatozoa) and embryonic death would ensue. The female reproductive tract has consequently developed at least three mechanisms for the prevention of polyspermy. These involve (1) selectively preventing sperm passage through the UTJ unless spermatozoa express an appropriate suite of proteins on their surface (calmegin, calreticulin, ADAM1a, 2, 3, and angiotensin converting enzyme, among others) (Cho et al., 1998; Ikawa et al., 2001, 2011; Shen et al., 2013); (2) hardening the zona pellucida through the action of oviductal proteins (e.g., oviduct-specific glycoprotein and heparin-like glycosaminoglycans), making it resistant to hydrolytic enzymes and turning it into a selective barrier that impedes the progress of spermatozoa towards the oocyte plasma membrane (Coy and Avilés, 2010; Coy et al., 2008); and (3) deploying intracytoplasmic hydrolytic enzymes sequestered in cortical granules situated beneath the oocyte plasma membrane to harden the zona pellucida still further after entry of the first, fertilizing, spermatozoon (Gadella and Evans, 2011; Puppo et al., 2008).

Ensuring that sufficient competent spermatozoa reach the vicinity of the egg, while simultaneously restricting the numbers and preventing polyspermy, requires delicate balancing mechanisms, but also provides scope for females to exercise a degree of choice. Compelling evidence for the existence of mechanisms that provide such choice has been provided by the use of heterospermic artificial insemination (HI). Highly controlled experiments conducted mainly on farm animals have demonstrated unequivocally that the female reproductive tract can significantly skew the outcome of AIs carried out by inseminating females with balanced sperm numbers taken from two or more males (for reviews, see Dziuk, 1996; Robl and Dziuk, 1988). This approach to relative fertility estimation eliminates female effects, such as the timing of insemination relative to ovulation and also eliminates the influence of relative sperm numbers. In some studies the skewed fertilization rates are as high as 97% in favor of one semen sample over another (Kasimanickam et al., 2006). In this study of bovine fertility, total progressive motility was positively correlated with the degree of skew but none of the other usual measures of sperm quality was significantly correlated. In similar vein, an HI study carried out with semen from two boars (Stahlberg et al., 2000) found a 70%–30% ratio of embryo paternity (95 embryos from 11 females were tested for paternity). When the same semen samples were used for homospermic inseminations there was no difference in the fertilization rates. Evidence of this nature implies that sperm selection *in vivo* is based on a complex molecular dialogue between the spermatozoa and the female reproductive tract.

In an effort to explain the mechanism responsible for the skewed fertility rates in cattle, Kasimanickam et al. (2006) found that the extent of skew was highly and negatively correlated with the DNA fragmentation rate in the semen samples (%DFI; $r = -0.87$; $P < 0.005$) while plasma membrane integrity (%PMI) was positively correlated ($r = 0.87$; $P < 0.005$) with the extent of skew. This study is of interest because it highlights the possibility that the female reproductive tract rejects membrane-damaged spermatozoa, but is then able to discriminate between the remaining intact cells on the basis of their DNA integrity. If this is true, it implies that membrane-intact spermatozoa somehow express membrane surface information about their DNA-status. Evidence that human cervical mucus acts as a filter capable of reducing the proportion of spermatozoa carrying fragmented DNA (Bianchi et al., 2004) supports the idea that the sperm surface mirrors sperm DNA status.

Hyaluronic acid has been also been found to assist with the formation of the oviductal sperm reservoir (Liberda et al., 2006; Rodriguez-Martinez et al., 2001). Once the spermatozoa gain access to the oviductal isthmus they exert some control over their

own environment. This was first noted by Ellington et al. (1993), who demonstrated that if cultured OEC are coincubated with spermatozoa, the epithelial cells respond by the de novo synthesis of proteins. Several follow-up studies in mice and pigs (Fazeli et al., 2004; Georgiou et al., 2007; Yeste et al., 2014) have lent support to these findings (for review, see Holt and Fazeli, 2010).

Conclusions

The term “sperm transport” understates the importance and complexity of the in vivo processes that ensue after ejaculation and culminate in fertilization. In fact, it could be argued that research conducted over the last two or three decades has revolutionized our view of sperm transport. Prior to this period, the female reproductive tract was largely regarded as a conduit, and the spermatozoa could simply make their way along it if their motility was good enough. Now it is understood that the sperm population in the ejaculate is essentially presented with a series of obstacles, and as the spermatozoa proceed via the cervix, uterus, and oviducts, perhaps becoming sequestered in epithelial glands or phagocytosed by polymorphonuclear leucocytes, their number is significantly depleted. Eventually a small remaining sperm population does, in fact, reach the vicinity of the oocyte and engage in fertilization. It has been estimated that the sperm:egg ratio within the oviduct at any given moment after ovulation may be as low as 1:1 (Hunter and Gadea, 2014), which presumably reflects the operation of stringent in vivo sperm selection mechanisms. The oviduct may be one of the most important sites for determining many aspects of sperm selection and competition as it possesses the potential for enhancing sperm survival, suppressing and activating sperm motility as required, and is now known to respond to the arrival of spermatozoa by producing novel proteins. Elegant proteomic experiments have even shown that the cohorts of novel proteins produced in response to the arrival of spermatozoa differ according to the sperm genotype (Almiñana et al., 2014). This implies that the spermatozoa are potentially responsible for establishing their own environment, and could certainly be involved in setting up the environment for optimal embryo development. Biochemical and biophysical studies of sperm motility have also revealed the existence of mechanisms that guide the spermatozoa towards the oocytes, probably using ancient mechanisms that may have initially evolved in marine invertebrates. Many puzzles remain to be solved, not least of which is how the female reproductive tract apparently has the ability to screen spermatozoa for their inherent genetic qualities, when sperm DNA is tightly and stably complexed with basic proteins (mainly protamines). Just as the last three decades have shown that sperm function is more complex than previously thought, it is likely that the next three decades will uncover yet more unsuspected but crucially important properties of spermatozoa.

Glossary

Infundibulum Funnel shaped ovarian end of the uterine tube.

Ampulla Relatively wide part of the tubular portion of the uterine tube, from the abdominal opening to the isthmus part.

Estradiol The primary female sex hormone produced primarily in the ovary.

Isthmus Narrow portion of the uterine tube after the ampulla and connecting to the uterus by the uterotubal junction.

Polyspermy A pathological condition in mammals consisting of the entrance of more than one spermatozoon in the oocyte, resulting in an aneuploid product.

Progesterone The hormone produced in the ovary and placenta necessary to prepare and keep a suitable environment for pregnancy in the female reproductive tract.

Zona pellucida Extracellular coat formed by glycoproteins that surrounds the oocyte and first stages of embryo divisions before implantation in mammals.

Anatomy of the Oviduct

Topography and Morphological Characteristics

The uterine tube (salpinx, oviduct, fallopian tube in humans) is a tubular, narrow, and sinuous structure with a length that can vary between species (approximately 10 cm in human species, 20 cm in sheep and horses, and about 25–30 cm in pigs).

It is located between the ovary and the uterus and is attached to the pelvic walls by a part of the broad ligament called mesosalpinx, which together with the oviduct itself and the proper ovarian ligament configures the ovarian bursa in most mammals, which surrounds the ovary (Fig. 1).

In its course five main parts are differentiated (Fig. 2). The first one, called infundibulum (i), is the closest to the ovary. It has a funnel shape, thin walls and irregular conspicuous folds, called tubular fimbriae, which converge toward the abdominal orifice of the tube. The infundibulum continues with a tubular portion composed of two main segments, ampulla and isthmus. The ampulla (ii) runs laterally to the ovary describing a sinuous trajectory that ends in a narrow ampullary–isthmic junction (iii) connecting with the isthmus. The isthmus (iv) is the caudal part of the uterine tube which communicates with the uterus through a uterine orifice in the so-called uterotubal junction (v). The three-dimensional architecture of this junction acts as a barrier or sphincter between the uterine cavity and the isthmus. While smooth and progressive in ruminants and pigs, it is abrupt in horses and carnivores so that the uterine tube protrudes within the uterine lumen with a small uterine papilla. In the particular case of the human species the isthmus

presents a transitional portion to join the uterus (uterine portion) which is a barrier not so functionally evident, as it will be seen later.

The inner morphology of the oviductal lumen is characterized by the presence of folds that are especially wide in the infundibulum and in the ampulla (**Fig. 3**). The largest ones or primary folds are arranged longitudinally along the whole length of the uterine tube. There are also smaller secondary folds with perpendicular disposition to the primary ones. Among the folds, there are deep grooves with sinuous pathways, and both structures together (folds and grooves) determine an irregular and highly complex lumen trajectory on the mucosa or endosalpinx (**Fig. 3A**). On the other hand, the number of folds is considerably reduced in the ampullary-isthmic junction, remaining only a few longitudinal folds in the isthmus, smaller and simpler than in the ampulla (**Fig. 3B**). In the ampulla and uterotubal junction, excavations are described in blind pouches and crypts, as well as elevations like polyps. These differences between the ampulla and the isthmus are related to functional aspects, as it will be seen later.

Fig. 3 Histological section of the mare oviduct stained with trichrome of Masson and viewed using light microscopy. (A) ampulla. The mucosa layer (Mu) presents numerous and big folds. Blood (arrows) and lymphatic vessels (arrowheads) are observed in the serosa layer (S). (B) isthmus. The mucosa layer (Mu) presents a important reduction of the number and size of the folds. The muscular layer (ML) is more developed in this region compared with the ampulla. Collagen fibers of the connective tissue present a green staining.

The reproductive status of the females as well as the phase of the reproductive cycle seem to influence the morphometric characteristics of the uterine tube. Thus, the length and its sinuous pathway increase in sexually adult females compared to prepubertal females, as well as among nulliparous and multiparous females. Similarly, the area of the oviductal lumen seems to be affected by these reproductive conditions. However, morphological aspects of the uterine tube, such as the length ratio between the ampulla and the isthmus, have been defined since puberty and are not affected by reproductive status or number of deliveries.

Vascularization and Innervation

In most of the domestic mammals the blood supply to the uterine tube comes mainly from the tubal branches of the ovarian and uterine arteries. These branches either form an extensive arterial network in the mesosalpinx before releasing terminal arterioles toward the mesotubarc border of the tube or directly terminate in the uterine tube with a minimal network of vascular anastomosis (Fig. 2).

The venous drainage of the uterine tube ends into the ovarian vein, as it does most of the blood from the uterus. The topography of the ovarian vein can be intimately related to the ovarian artery, which allows arteriovenous connections that are considered responsible for the local counter-current transfer of luteolytic substances between the uterus and ovary. In these large contact areas, the wall's thickness of the arteries and veins is diminished, specifically in adventitia where the fascicles of connective tissue form a single layer, which facilitates communication.

The lymphatic vessels of the uterine tube drain into the subserous and mucosal plexus and end up in the mesovary where they join the lymphatic vessels from the uterus and ovary. Together with the arteries and veins a periovaric vascular complex is described, which functionally interact creating a specific environment for physiological processes such as the mentioned hormone counter-current transfer.

Certain phases of the reproductive cycle may result in significant increases in vascular supply to the uterine tube as well as to the uterus and ovary. However, it has been found in the sow that the number of terminal arterioles reaching the ampulla or the isthmus does neither vary between prepubertal and adult females nor affect the phase of the reproductive cycle. Therefore, the increase of vascularization during the reproductive cycle is supposed to be mainly due to vasodilation phenomena.

Innervation is provided by sympathetic and parasympathetic nerves from the autonomic nervous system. Branches from the aortic plexus, that accompanies the ovarian artery, to innervate the ovary, and branches from the pelvic plexus supply the female genital tract.

Histology of the Oviduct

The oviduct is formed by three layers with a predominant or characteristic tissue. Thus, internally, a mucosa layer is present formed by an epithelium. The middle layer is the muscular layer formed mainly by smooth muscular cells and the external layer is the serosa formed mainly by connective tissue. The size and organization of these three layers is different depending on the region of the oviduct, the species and, to some extent, the phase of the estrus cycle.

Main Layers

The mucosa layer (Fig. 3), covering internally the oviduct, is formed by a simple epithelium of columnar or cuboidal cells that rest on a basal lamina. Below this, a connective tissue called lamina propria is present. Regarding the muscular layer (Fig. 3), two different types of structure can be observed in the ampulla and isthmus. It was observed in some species (rabbit, cow, sow, ewe, and woman) that the extrinsic and intrinsic components of the muscular layer are closed intermingled showing a plexiform architecture. However, in the rat, both musculatures are independent.

In the uterotubal junction, the myoarchitecture allows the classification in two main groups: a barrier-like and a sphincter-like structure. In the barrier-like structure, the smooth muscle fibers are densely packed (e.g., rat and sow). In the sphincter-like structure, the smooth muscle fibers can be geometrically organized (e.g., rabbit and ewe) with an independent relationship among the extrinsic and intrinsic musculature or with a plexiform organization (e.g., cow and woman) with a closely interwoven between both musculatures.

The serosa layer is formed by a simple squamous epithelia of mesothelial cells which cover externally the oviduct. A submesothelial connective tissue is observed which contains blood and lymphatic vessels. It can also be observed the presence of cholinergic and adrenergic nervous fibers which modulate the activity of the muscular layer.

Main Cells in the Oviductal Epithelium in the Mucosa

The epithelium covering the lumen of the oviduct is mainly formed by two types of cells: ciliated and secretory cells. The ciliated cells are characterized by the presence of a high number of motile cell prolongations called cilia that are formed by tubulin protein. The number of ciliated cells is different in the different regions of the oviduct with a lower number of cells in the isthmus (Fig. 4), and this number varies depending on the phase of the reproductive cycle, with the ciliated cells increasing around the ovulation time. In the human fallopian tube, the ciliated cells can be up to 80% in the fimbriae close to the ovary and 30% in the isthmus.

Fig. 4 Bovine oviduct. Scanning electron microscopy image showing the ciliated (Ci) and secretory (SC) cells of the oviductal epithelium.

The cilia move coordinately in the same direction and participate in the movement of the oocytes and embryos in direction to the uterus.

The secretory cells are dispersed among the ciliated cells, and the main characteristic is the presence of abundant secretory granules in their apical region that are released to the oviductal lumen mainly by exocytosis. At the surface of the cell, short immotile prolongations called microvilli are present. Recently, it was observed the presence of unique nonmotile cilia in these cells known as primary cilia. It was demonstrated that these primary cilia function as antennae for sensory reception and consequently provide information about the oviduct lumen. However, it was recently reported that the motile cilia, not only the primary cilia, are also involved in the sensory mechanism.

Oviductal Fluid's Composition

The oviductal fluid is the result of the specific secretions from the oviductal epithelial cells and the transudation from the blood. Although similar to the blood plasma, it shows some differences regarding electrolytes, amino acids, and carbohydrates proportions, among others. It contains glycosaminoglycans and a large number of proteins including some specific proteins only found at this organ, being the oviduct-specific glycoprotein (OVGP1) the best known and studied. The most abundant protein present in the oviductal fluid is the albumin which is originated in the liver and transported by the blood to the oviduct. Albumin plays an important role in the capacitation of the sperm by removal of the cholesterol from the sperm plasma membrane. Other important proteins contained in the oviductal fluid are growth factors that contribute to the efficient development of the early embryos by favoring the cell division. Another important group of proteins are proteases and their inhibitors whose key functions were revealed recently. Thus, in the oviductal milieu a well regulation of the proteolysis is produced which avoid the death of the oocyte and embryos. An additional more complex component present in the oviductal fluid consists of extracellular vesicles which are released by cells in the oviductal lumen and serve as vehicles for the transfer of lipids, proteins, and RNA. These extracellular vesicles can be differentiated according to their size in exosomes (40–100 nm) and microvesicles (50 nm–1 μm). Recently, these extracellular vesicles have been reported to modify the gametes and the embryo and even contribute to the maternal-embryo communication.

Oviductal Functions

According to the ovarian morphology, explained in previous chapters, the reproductive cycle of most of mammals, including primates, could be divided in two phases. The follicular phase is that in which the predominant structure observed in the ovary is the single (or are the multiple) follicle(s) growing (Fig. 5A), depending on the typical number of offspring delivered in each species. The luteal phase is that in which the corpora lutea, resulting from the transformation of the follicles after ovulation, can be observed. Ovulation, on the other side, is a process occurring between the follicular and the luteal phase of the cycle. While the ovarian follicles produce estradiol by means of the granulosa cells covering their internal wall and supporting the oocyte inside, the cells of the corpora lutea produce progesterone, the so-called hormone of pregnancy. All the events happening in the oviduct are regulated and orchestrated by these changing ratios of estradiol/progesterone.

The phase of the reproductive cycle in which the oviductal physiology acquires its maximum importance is that comprising the end of the follicular phase and the beginning of the luteal phase. At the end of the follicular phase the surge of LH is triggering the

Fig. 5 Diagrammatic representation of the oviductal regions and their different functions. (A) The oocyte is released from the preovulatory follicle in the ovary. (B) The oocyte enters the oviduct through the infundibulum. (C) Spermatozoa and oocyte meet at the ampullary–isthmic junction and fertilization occurs. (D) After the first mitosis, the zygote divides into two cells. (E) The embryo proceeds through the isthmus while the divisions progress. (F) Hours or minutes before the arrival of the oocytes, the spermatozoa are retained in the isthmus by binding to the ciliated cells in the epithelium forming the sperm reservoir. (G) The embryo reaches the uterus and look for a place for implantation.

important hormonal changes (drop of the estradiol levels and increase of the progesterone) that modify the whole reproductive tract, for example, reshaping the mucosal epithelium from the oviduct, through the uterus until to the vagina or reverting the sense of the muscular layer contractions. In the oviduct in particular, as it has been explained in the histology section, the proportions between secretory and epithelial cells in the mucosa change depending on the estrogen/progesterone ratio and so does the composition of the fluid bathing the lumen of the oviduct. During these days, the crucial events taking place in this organ include the ovulation and oocyte transport, the end of the sperm capacitation, the fertilization, the first embryonic divisions (cleavage), and finally, the entrance in the uterus of the recently formed conceptus.

In the next three sections, the events occurring in the oviduct between the end of the follicular phase and the beginning of the luteal one are described.

Events Happening in the Oviduct Before Fertilization (End of Follicular Phase)

In Fig. 5, the different functions of the oviduct are represented. Just after ovulation (Fig. 5B), the cilia-covered fimbria of the infundibulum are responsible for the process of ovum-catchment, which, in most cases, is 100% effective. This is so because, around the ovulation time, the coordination between the nervous and hormonal systems makes this free end of the oviduct approach to the ovary. This movement is favored by the spontaneous contractions of the smooth muscular fibers in the oviduct wall that couple with phasic contractions of the myosalpinx. It seems that oviduct interstitial cells of Cajal display pacemaker activity by electrical slow waves coordinating these contractions. Once in the oviduct, the oocytes must be transported to the distal end of the ampulla. Together with the oviductal contractions, ciliary beating is crucial for this event. At this stage, the oocyte is still surrounded by the cumulus cells, and the level of adhesion of these cells to the infundibulum wall is depending on the extent of cumulus expansion. If this extent is very high, then the adhesion can be stronger and the transportation turns difficult. Oocytes surrounded by the cumulus cells (oocyte–cumulus complexes) reach the ampullary–isthmic junction (Fig. 5C) relatively soon (30–45 min), and their level of coupling is diminishing during the transport. The presence of spermatozoa in the oviduct accelerates cumulus cells dispersion. The contact of the oocytes with the oviductal fluid during this time is also important to induce modifications at the zona pellucida level that will influence the initial recognition and binding of the spermatozoa.

Hours or minutes before the arrival of the oocytes, the spermatozoa have usually reached the isthmus and are retained there by their binding to the ciliated cells in the epithelium forming the sperm reservoir (Fig. 5F). This retention is important for the sperm to finish their capacitation process, which enable them to fertilize the oocyte. It seems that the presence of cumulus–oocyte complexes in the ampulla contributes to the release of the spermatozoa from the sperm reservoir, thus reinitiating their journey to the fertilization site, at the ampullary–isthmic junction, where they finally meet the oocyte. Spermatozoa released from the reservoir show a specific motility pattern characterized by a very vigorous flagellar beating called “hyperactive motility.” This pattern is necessary for the fertilization.

Fertilization

Fertilization consists of the fusion of male and female gametes at the ampullary–isthmic junction of the oviduct to form the zygote (Fig. 5C). The oviduct favors the rendezvous of both gametes and provides a fine-tuned environment to avoid failures in this crucial event. As example of its perfect coordination, not only its tubular structure, the proportions between secretory and epithelial cells in the mucosa, or the spontaneous and phasic contractions of the smooth muscular fibers in the oviduct wall contribute to avoid the massive arrival of spermatozoa to the oocyte's proximity, but also the oviductal fluid, inducing modifications at the zona pellucida level, is responsible for regulating the pathological condition of polyspermy in mammals.

Events Happening in the Oviduct After Fertilization (Beginning of Luteal Phase)

Once the zygote is formed, it remains in the ampullary–isthmic junction for a few hours until the first cleavage takes place and it divides into two cells (Fig. 5D). Then, the two-cells embryo restarts its journey and slowly shifts along the isthmus. The thick muscular layer at this region, which was heavily contracted under the influence of estradiol, is now relaxed by the effect of progesterone, allowing the embryo proceeds while the divisions progress (Fig. 5E). The rich product of the secretory cells in the epithelium makes the fluid dense and keeps the perfect environment for the embryo survival, providing the necessary nutrients for the recently formed conceptus. Depending on the species, the entrance in the uterus through the uterotubal junction occurs approximately at the 4 cell stage on day 2–3 postfertilization (e.g., in the pig) or at more advanced stages on day 4–5 after fertilization (e.g., at the morula stage in the human) (Fig. 5G).

Fallopian Tube/Oviduct: Structure and Cell Biology

Wipawee Winuthayanon and Shuai Li, Washington State University, Pullman, WA, United States

© 2018 Elsevier Inc. All rights reserved.

Glossary

Axoneme The central strand of a cilium or flagellum. It is composed of an array of microtubules, typically in nine pairs around two single central ones.

B cells A type of lymphocyte developed from stem cells originated from bone marrow; responsible for producing antibodies and participating in the immune response.

Cell atrophy Decrease in size of the cells.

Ectopic pregnancy Embryo implants somewhere other than the main cavity of the uterus.

Fimbriae A series of fringe-like structure at the ovarian end of the Fallopian tube.

Polyspermy An egg fertilized by multiple sperm, this will lead to embryonic cell death.

T cells A type of lymphocyte produced or processed by the thymus gland and actively participating in the immune response.

Transudation Passage of the fluid through cell membrane as a result of osmotic pressure.

Zygote A fertilized egg or one-cell embryo.

Gross Anatomy

The human Fallopian tubes (known as oviducts in animals) are part of the female reproductive tract and are responsible for gamete (egg and sperm) transport. The Fallopian tube is the site for fertilization and preimplantation embryo development. Progressing from the ovary to the uterus, the three distinct segments of the Fallopian tube are infundibulum, ampulla, and isthmus (Fig. 1).

Fig. 1 Illustration of one side of the human female reproductive tract, including ovary, Fallopian tube, uterus, cervix, and vagina. The fimbria of infundibulum comes in contact with the ovary during ovulation to enable the Fallopian tube to pick up the eggs. The ampulla is the fertilization site and connects to the isthmus region of the Fallopian tubes. The isthmus is adjacent to the uterus and connected through the uterotubal junction. The Fallopian tube is supported by connective tissue embedded with vascular, nervous, and lymphatic system known as the mesosalpinx.

Each segment in the Fallopian tube has distinct cell morphology and function. The infundibulum is a trumpet-like segment of the Fallopian tube. The fimbriated end of the infundibulum opens up to the peritoneal cavity. Fimbriae are lined with multiciliated epithelial cells with a threadlike extension toward the ovary. These multiciliated epithelial cells of the infundibulum function to aid oocyte pickup and transport. The ampulla represents two-thirds of the length of Fallopian tube and is the site for fertilization of oocytes. The proportionality of epithelial cell lining in the infundibulum and ampulla gradually changes from ciliated cell population to secretory cell population in the isthmus, the final segment of the Fallopian tube. The wall of the isthmus is thicker and more resistant to palpation than the ampullary region.

Segments of the Fallopian tube are connected with three junctional areas: fimbria abdominal ostium, ampullary–isthmic junction, and uterotubal junction. The fimbria is a fingerlike structure surrounding the infundibulum and extending outward from the Fallopian tube. The fimbria abdominal ostium is the opening that connects the Fallopian tube with the peritoneal cavity. The largest fimbria, called the ovarian fimbria, is attached to the ovary. At ovulatory phase, the luteinizing hormone peaks, causing the follicle to rupture. The oocyte–cumulus complex is then released from the ovary and picked up by a fluid current generated from ciliated epithelial cells beating on the surface of the fimbria. Ciliary movement transports oocyte–cumulus complex further deep into the Fallopian tube toward the uterus. Aptly named, the ampullary–isthmic junction is a junction between the ampullary and isthmic region of the oviduct. This junction is identified by an abrupt change in muscle wall thickness between the ampulla and the isthmus. The ampullary–isthmic junction regulates the delay of ovum transport, allowing sperm to advance into the ampulla in a timely manner (Anand and Guha, 1982). Lastly, the isthmus joins the uterus via the uterotubal junction. This junction serves as a selective sperm barrier, allowing only viable sperm to advance to the site of fertilization.

There is a recognized anatomical distinction between species. Human Fallopian tubes, rabbit oviducts, and nonhuman primate Fallopian tubes have a slight curve in their structure. Other animals such as rodents, birds, and amphibians have a coiled structure. This difference is a developmental characteristic, but the mechanism for coiling or curvature is still not well understood (Stewart and Behringer, 2012). Despite the anatomical differences between species, the Fallopian tubes of mammals consist of the same three main structural layers (Fig. 2A): mesosalpinx (outer serous layer), myosalpinx (muscle layer), and endosalpinx (mucosa layer).

Physiological function of the Fallopian tubes is regulated mainly by estrogen (E_2) and progesterone (P_4), two major sex steroid hormones. E_2 and P_4 signals through estrogen receptors and progesterone receptors to control tubal muscle contraction, ciliary beat frequency of the ciliated epithelial cells, secretory factors from the nonciliated epithelial cells, and other cellular

Fig. 2 Histological images of a human Fallopian tube in comparison with a mouse oviduct. Epithelial cells comprise two cell types: ciliated and nonciliated (or secretory) cells, facing the lumen.

functions to optimize the microenvironment for reproductive events in the Fallopian tube. This topic will be discussed in detail in the following sections.

Cell Biology and Physiology of the Fallopian Tube

Mesosalpinx

Serous layer of the Fallopian tube, also known as mesosalpinx (**Fig. 2A**), is the outer tissue layer that wraps around the Fallopian tube and is part of the peritoneal cavity lining. Mesosalpinx is composed of epithelial cells of mesothelium and a mesh of serous membrane lining (interstitial connective tissue). The mesothelium is the outermost boundary of the serous layer and is directly exposed to the pelvic cavity. Underneath the mesothelium is the serous membrane, surrounding the muscle layer. Blood vessels, nervous system, and lymphatic system are located within the serous membrane (**Pauerstein and Eddy, 1979**).

The vascular system of the Fallopian tube is supplied by the uterine and ovarian arteries. The capillaries innervate into the muscle and mucosal layers (**Fig. 2A**). This vascular system not only is critical for circulation but also is crucial for embryo development (**Garcia-Pascual et al., 1996**). Blood flow in the Fallopian tube is responsible for the generation and maintenance of the tubal fluid, which nourishes and protects gametes and embryos against external stress.

The nervous innervation of the Fallopian tube depends on the segment and the type of sensory nervous system. For example, the sympathetic nervous system from the celiac plexus innervates the infundibulum and the ampullary portion adjacent to the infundibulum, whereas the ampullary portion adjacent to the isthmic region and the isthmus receive sympathetic nervous supply from the inferior mesenteric plexus. For the parasympathetic nervous system, similar areas of the infundibulum and the ampulla are innervated by ovarian plexus, and similar areas of the isthmus and part of the ampulla are innervated by pelvic plexus of the pelvic nerve. Innervation of the nervous system runs parallel with the vascular system.

The lymphatic system of the Fallopian tube is supplied by the ovarian and uterine lymphatic systems, which originate from the iliac and lateral aortic nodes. Lymphatic system runs into the serous and mucosal layer enabling the lymphocyte to infiltrate and protect the Fallopian tube from pathogen infection. In the Fallopian tube, the lymphatic system acts as a drainage to reabsorb tubal fluid. The major immune cells found in the Fallopian tubes are the T cells. B cells are rare in this tissue (**Otsuki et al., 1989**).

Myosalpinx

Myosalpinx is the tubal muscle of the Fallopian tube, which consists of an outer longitudinal muscle layer and an inner circular muscle layer. These two muscle layers control the Fallopian tubal contraction responsible for various reproductive functions. First, the contraction retains the unfertilized oocyte in the ampullary region of the Fallopian tube. This is achieved through contraction of the muscle in the ampullary–isthmic junction. Ampullary–isthmic contraction also prevents polyspermy by restricting the rate of the sperm entering the ampulla (**Ezzati et al., 2014**). Both the ampullary–isthmic junction and uterotubal junction are pivotal for the timing of embryo implantation in the uterus. It takes the oocyte approximately 8 h to reach the ampullary–isthmic junction; then, after fertilization, the zygote is retained in the isthmus for approximately 72 h (**Croxatto et al., 1978; Lyons et al., 2006**). However, the time an embryo spends in the Fallopian tube is species-specific (**Croxatto, 2002**). Overaccelerated embryo transport results in premature arrival of the embryo to the uterus, in which the uterine environment is not conducive for embryo implantation (**Adams, 1979**).

Unlike intestinal smooth muscle, muscle contraction of the Fallopian tube not only is controlled by adrenergic neurons but also is regulated by P_4 and prostaglandins (**Wanggren et al., 2008**). Progesterone and prostaglandin receptors have been recently identified on the telocyte, a newly discovered cell type in human Fallopian tubes (**Cretoiu and Cretoiu, 2016**). Telocytes are interstitial cajal-like cells with long cytoplasmic processes (**Cretoiu et al., 2009**) that reside in the interstitial connective tissue layer of the Fallopian tube. The function of telocytes is not yet fully understood. However, evidence indicates that a reduction in telocytes results in defective peristaltic movement of the Fallopian tube (**Roatesi et al., 2015**).

Endosalpinx

Endosalpinx is the inner mucosal layer of the Fallopian tube responsible for transporting gametes and embryos and tubal fluid secretions. The endosalpinx is composed of epithelial cells and the lamina propria mucosa; the latter is a network of connective tissue with a mixed cell population. The epithelial tissue on the inner surface of the Fallopian tube is made up of two main cell types: ciliated epithelial cells and nonciliated secretory epithelial cells (**Fig. 2B and C**). Beneath the lining of epithelium is the lamina propria, which consists of fibroblast, immune, and progenitor cells. Mucosal layer forms dense internal folds, increasing the surface area of epithelial cell lining to achieve high fluid secretory rate (**Fig. 2A**).

Multiciliated epithelial cells in the Fallopian tube are featured with a classical 9 + 2 microtubule structure (axoneme) to create a beating movement (**Lodish et al., 2000**). The movement of axoneme requires adenosine triphosphate (ATP) as the energy source. Elevated E_2 concentration stimulates ATP production at the apical surface of the epithelial cells and results in an increase in ciliary beat frequency. In rabbits, the absence of calcium results in nonbeating cilium. This suggests the mechanism involves a calcium-dependent ciliary regulation (**Verdugo, 1980**), potentially through a voltage-gated calcium

channel (Doerner et al., 2015). Adrenomedullin-induced activation of calcitonin-gene-related peptide receptor is also involved in ciliary beating (Liao et al., 2013; Liao et al., 2011). In this adrenomedullin-related mechanism, E_2 stimulates the secretory epithelia to produce cyclic adenosine monophosphate, which subsequently promotes adrenomedullin activation in ciliated cells.

Nongenomic membrane-bound progesterone receptors (mPGRs) have been observed on the apical surface of epithelial cells in the Fallopian tube. mPGRs facilitate rapid cellular signaling pathways activated by P_4 and regulate ciliary beat frequency. Therefore, an alteration of these pathways could cause defective ciliary function and lead to embryo transport defects.

Ciliary beat activity of the epithelial cells results in oocyte pickup, embryo transport, and tubal fluid flow. Tubal fluid flow acts as a carrier, allowing embryo transport from the Fallopian tube to the uterus. Simultaneously, the fluid flow removes cell debris within the lumen (Miki and Clapham, 2013). The direction of the fluid flow is usually from the ovary toward the uterus in mammals. However, tubal flow in pigs progresses toward the ovary, which suggests that fluid flow orientation varies between species (Gaddum-Rosse and Blandau, 1976).

Approximately, 60% of epithelial cell lining is nonciliated epithelial (secretory) cells. The percentage differs between tube regions (Pedrero-Badillo et al., 2013). These secretory epithelial cells are morphologically distinct from ciliated epithelia. Not only the nonciliated epithelial cells lack cilia at the apical membrane, but also the cell bodies show apical protrusion into the lumen, also known as intercalary cells or peg cells (Fig. 2B and C). The cytosol of secretory cells contains an extensive Golgi network and apical granules. Secretory cells mainly secrete growth factors, nutrients, antimicrobial agents, and anticellular stress agents into the tubal fluid. Some of the secretory factors are enzymatically active including proteases and peptidases, which could potentially harm the embryos. Recent findings demonstrate that E_2 can have a protective effect on the embryo by reducing protease production within the mouse oviduct (Winuthayanon et al., 2015).

The lamina propria mucosa consists of connective tissue, secretory cells, microcapillary vessels, and a population of leucine-rich repeat-containing G-protein-coupled receptor 5 (LGR5)-positive progenitor cells. Lamina propria provides structural and nutritional support for the endosalpinx, while Lgr5-positive progenitor cells allow for tubal epithelial cell regeneration (Ng et al., 2014; Snegovskikh et al., 2014).

Tubal Fluid

Tubal fluid is composed of transudation from circulating plasma and secretions from the secretory epithelial cells. After ovulation, follicular fluid is combined with tubal fluid. Main functions of the tubal fluid are facilitating sperm transport and providing nutrients, growth hormone, protective agents for the embryo, and defense system against pathogens (Guerin and Menezo, 2011). In addition, the mucosal layer removes cell debris such as sperm, macrophages, bacteria, and dead epithelial cells (Miki and Clapham, 2013).

Fluid composition in the Fallopian tube is listed in Table 1. Tubal fluid contains glycoproteins and amino acids, with the most abundant nutritional compositions in the fluid being lactate (3–10 mM), glucose (0.2–1.9 mM), and pyruvate (0.02–0.2 mM). The most abundant amino acids are arginine (0.19 mM), alanine (0.11 mM), and glutamate (0.09 mM) (Dickens et al., 1995; Tay et al., 1997). The listed nutrients are used primarily by oocytes and embryos, while the excessive nutrients are reabsorbed and used by cells in the Fallopian tube. In general, protein concentration in the tubal fluid changes during the menstrual cycle and reaches the maximal concentrations at the time closest to menstruation. This dynamic change in protein concentration alters fluid viscosity and impacts the rate of tubal flow. The transient receptor vanilloid 4 (TRPV4) on epithelia cells detects fluid viscosity and regulates ciliary beating (Andrade et al., 2005). A viscous fluid in the Fallopian tube during fertilization stabilizes tubal microenvironment and protects the embryo against osmotic changes (Leese et al., 2001).

Growth factors in the tubal fluid include epidermal growth factor, embryotrophic factors, transforming growth factor, insulin-like growth factor, and fibroblast growth factor. Coculture of the embryos with these growth factors improves embryo development (Coy and Yanagimachi, 2015; Kane et al., 1992). Several embryo protective factors are present in the fluid, including heat shock protein, taurine and its derivatives, catalase, and antioxidative enzymes (Guerin and Menezo, 2011). Embryo protective factors prevent both gametes and embryos from environmental stress including, heat, free radicals, and internal and external reactive oxygen species.

Infection causes damage to Fallopian tube structure and function and can subsequently lead to complications in pregnancy. For example, gonococcal (gonorrhea) and chlamydia infections in the Fallopian tube cause ciliated cell damage, resulting in a loss of ciliary beat activities (McGee et al., 1981). Fortunately, the maternal immune system has macrophages patrolling within the tubal fluid to protect against microbial invasion. Fallopian tube secretory epithelial cells also produce cytokine/interleukin signal to induce inflammatory response (Maisey et al., 2003). Additionally, tubal fluid flow mechanistically eliminates unwanted bacteria and cell debris to the lower reproductive tract. In conclusion, the tubal fluid promotes fertilization, supports early embryo development, and maintains an optimal microenvironment in the Fallopian tube against pathogen invasion.

Cell Distribution in Different Regions of the Fallopian Tube

Each segment of the Fallopian tube serves a distinct function; therefore, structural and cellular compositions vary in each region. Two major structural differences are the muscle cell layer and the distinct epithelial cell distribution along the Fallopian tube. Less

Table 1 Known tubal fluid composition and their roles. Water and soluble gas are omitted from the table

<i>Roles</i>	<i>Components</i>
Embryo energy source	Pyruvate Lactate Lipids and fatty acid Amino acids Glucose and sugar glycogen
Fertilization-related	Oviductin (OVGP1) Plasmin Fetuin B
Sex steroid hormones	Estrogen Progesterone
Glycogen–sugar conversion	Amylase
RNA synthesis	HCO ₃ [−]
Growth factor	Embryotrophic factor 3 Epidermal growth factor (EGF) Transforming growth factor (TGF) Fibroblast growth factor (FGF) Insulin-like growth factor (IGF)
Antioxidants	Glutathione (GSH) Taurine Hypotaurine Cysteamine Catalase Superoxide dismutases Glutathione peroxidases
Antiheat stress	Heat-shock protein 70 Heat-shock factors
Antimicrobial	Serine proteases and inhibitors Defensins Cytokines
Muscle contractility	Endothelin, increase contractility Prostaglandins, depends on receptors Estrogen, increase contractility Progesterone, decrease contractility
Ciliary beat frequency (CBF)	Adrenomedullin, increase CBF Estrogen, increase CBF Progesterone, decrease CBF

muscle cells are present around the infundibulum and more abundant in the isthmic end of the tube (**Fig. 3**). A high percentage of ciliated epithelial cells are found at the infundibulum end, while the isthmic end is predominantly composed of secretory cells (**Pedrero-Badillo et al., 2013**). This is believed to be the evolutionary result of functional differences between the two ends of the tube. The infundibulum end is responsible for oocyte pickup and transport of the embryo; hence, it has more ciliated cells and less muscle cells than the isthmic end. A lack of muscle contraction in the infundibulum leads to a gentle motion, which allows smooth transition of the oocyte or embryos in the Fallopian tube (**Croxatto, 2002**). Strong muscle contraction at the isthmic end is due to the abundance of muscle fibers in this region. The mechanical control of muscle contraction at the isthmic region, together with the ampullary–isthmic junction and the uterotubal junction, allows embryo retention inside the Fallopian tube during the first few days of early development (**Halbert et al., 1988**).

Influences of E₂ and P₄ on Fallopian Tube Physiology and Function

In mammals, Fallopian tube physiology is significantly influenced by E₂ and P₄. Fallopian tube tissue displays a cyclical structural change in correlation with circulating levels of E₂ and P₄ during the menstrual cycle. Granulosa cells in the ovary produce E₂, in which the circulating level peaks during follicular phase of the menstrual cycle, right before ovulation, then decreases gradually during the luteal phase (**Fig. 4**). E₂ exerts its activity through estrogen receptor alpha (ESR1) and beta (ESR2). ESR1 is located in all layers of the Fallopian tube, and ESR2 presence is limited to some of the epithelial cells. E₂ increases epithelial cell hypertrophy, production of secretory proteins from the secretory cells, and ciliogenesis (**Verhage et al., 1979**) (**Fig. 4**). In humans, however, E₂ and P₄ work together to regulating ciliary beat frequency of the ciliated cells (**Mahmood et al., 1998**).

Fig. 3 Changes in cell population and tissue characteristics along the infundibulum, ampullary, and isthmic regions of the Fallopian tube. Ciliated epithelial cells and epithelial (mucosal) folds are highly abundant in the infundibulum and ampullary regions and gradually declined in the isthmic region. Isthmic region has high proportion of secretory epithelial cells and muscle thickness compared with the infundibulum and ampullary regions. Note that the figure does not reflect the actual percentile of the cell population proportion, but rather a general trend.

Fig. 4 The effects of circulating 17 β -estradiol (E_2) and progesterone (P_4) on cell morphology, ciliary beat frequency, and muscle contraction in Fallopian tubes during the follicular and luteal phases.

In mammals, P_4 is mainly secreted from the cumulus cells surrounding the oocyte. The circulating level of P_4 increases after ovulation and then declines at the end of the luteal phase. P_4 binds to progesterone receptors (PGRs), classical nuclear PGR-A and PGR-B, and membrane-bound PGRs. Classical PGRs respond to P_4 to decrease muscle contraction and ciliary beat frequency (Wanggren et al., 2008; Bylander et al., 2013). Membrane-bound PGRs (also known as membrane-bound progestin receptors, mPRs) are a family of PGR proteins recently discovered that consist of three members in humans and other vertebrates known as mPR α , mPR β , and mPR γ . The mPRs are localized mainly in the membrane of the cell and endoplasmic reticulum, and the expression of mPRs is tissue-specific (Kowalik et al., 2013). In humans and mice, mPR β is exclusively expressed in the cilia, whereas mPR γ primarily resides at the cilia basal area. Expression of mPRs in the Fallopian tube is regulated by P_4 and E_2 (Nutu et al., 2009). However, the function of these membrane-bound PGRs is still unclear.

In summary, E_2 promotes embryo transport by increasing epithelial cell hypertrophy, causing fluid secretion (Hamner and Fox, 1968), subsequently elevating ciliary beat frequency to induce a high rate of flow, and increasing the rate of muscle contraction

(via inhibition of P_4 activity) (Mahmood et al., 1998) (Fig. 4). P_4 induces deciliation (a loss of cilia on the ciliated epithelial cells), cell atrophy, and loss of secretory activity in secretory epithelial cells (Donnez et al., 1985; Pedrero-Badillo et al., 2013). Loss of secretory activity leads to a reduced fluid influx, resulting in viscous tubal fluid that slows the rate of embryo transport. When both E_2 and P_4 drop to basal levels, secretory epithelial cells restore their secretory activities, and ciliary cells regain ciliation for the next menstrual cycle (Verhage et al., 1979).

Health Condition Related to Defective Fallopian Tube

The most relevant health condition related to Fallopian tube defect is the ectopic pregnancy. Ectopic pregnancy is a form of abnormal gestation where a fertilized egg implants in tissues other than the endometrium of the uterus. During the early 2000s in the United States, 1%–2% of all pregnancies were ectopic, a dramatic increase from 0.4% in 1948. Many developed countries in Europe have also observed a doubling incident rate of ectopic pregnancies from the 1970s to 1990s.

The most common ectopic pregnancy site (>98%) is in the Fallopian tube. Among tubal ectopic pregnancies, one-third of the cases are associated with smoking, which damages ciliary function (Farquhar, 2005). Less than a third of tubal ectopic pregnancies are caused by tubal damage that can be sustained from infection or surgery. These physical damages disrupt muscle and ciliary function and lead to impaired embryo transport. Remaining cases are diagnosed with an unknown cause. Though deaths associated with ectopic pregnancy have declined due to advancement in medical improvement. However, it is still the most common maternal mortality with a morbidity rate of 9%–13% of all pregnancy related death during the first trimester. The mortality rate caused by ectopic pregnancy is much higher in developing countries (Shaw et al., 2010b).

Women with ectopic pregnancies have a reduced number of ciliated cells, suggesting that defective cell proliferation or differentiation could alter pregnancy outcome (Vasquez et al., 1983). Regarding molecular mechanisms, nitric oxide synthase (iNOS), prokineticins, cannabinoid receptors, mucin proteins, and immune system signaling pathways all are shown to be associated with the etiology of ectopic pregnancy (Shaw et al., 2010b). Women with ectopic pregnancy briefly have a higher level of iNOS in their Fallopian tube tissue. iNOS can alter tubal contractility and possibly ciliary beat frequency through the induction of nitric oxide (Vasquez et al., 1983; Al-Azemi et al., 2010). Prokineticins regulate smooth muscle contraction, and women with ectopic pregnancy show a reduced expression level of prokinetics (Maldonado-Perez et al., 2007; Shaw et al., 2010a). Interestingly, a defective cannabinoid receptor signaling pathway in mice causes embryo retention (Wang et al., 2004; Horne et al., 2008). A glycoprotein called mucin 1 (MUC1) is expressed in the epithelial cells of female reproductive tract. Epithelial mucin expression is normally suppressed to promote the embryo attachment in receptive uteri. In women with ectopic pregnancies, it is shown that expression of MUC1 is decreased in the tubal epithelial cells (Al-Azemi et al., 2009). Infection and inflammation can also induce high levels of interleukins and leukemia inhibitory factor (LIF), which promote tubal implantation of the embryo (Buchholz and Stephens, 2007; Guney et al., 2008). Several other signal pathways involved in the ectopic pregnancy are discussed in a comprehensive review (Shaw et al., 2010b).

Summary

This chapter summarizes what is known about the structure and function of the Fallopian tubes. The three segments of the Fallopian tube—mesosalpinx, myosalpinx, and endosalpinx—are described in details with basic cell biology and physiology. The article also summarizes the content and functionality of the tubal secretion and the cellular difference between each region. Sex steroids estrogen and progesterone influencing the physiology and the function of Fallopian tube are discussed. Lastly, we included the most common health condition related to pregnancy complication resulted from defective Fallopian tube—ectopic pregnancy. This condition impacts 1%–2% of pregnancies in the United States.

Introduction

Sexual reproduction and genetic diversification are foundations for evolutionary success to ensure perpetuation of the species by selecting for traits optimal for survival. Along this vein, mammalian pregnancy involves dynamic changes within the hormonally responsive pregnant uterus, nascent embryo, and transiently-lived mosaic tissues that promote their growth and reciprocal interactions. This involves the complex sequence of embryo development and implantation, decidualization, placentation and finally birth of offspring through the process of parturition (Dey et al., 2004; Lim and Wang, 2010; Cha et al., 2012). While the success of each event is critical for advancement to the next stage, the hierarchical directives that orchestrate embryo-uterine crosstalk are not fully characterized. These events are primarily directed by ovarian estrogen and progesterone (Dey et al., 2004); however, the molecular dialogue between the mother and embryo governing the orderly transitions of pregnancy events is yet to be fully understood.

The uterus is embryologically derived from the intermediate mesoderm and Mullerian ducts, which fuse at their caudal ends and differentiate to form the distinct cell types of the myometrium and the endometrium (Finn and Porter, 1975). The endometrium is hormonally responsive to ovarian hormones and comprised of the luminal epithelium, stroma and interspersed tubular glands which open and release contents into the uterine lumen. While the majority of endometrial cell types are defined during development, gland formation occurs postnatally from the uterine lumen as invaginations projecting toward the antimesometrial domain and is believed to be hormonally mediated (Filant and Spencer, 2014). A recent study shows that a differential Wnt gradient at the mesometrial (M) and anti-mesometrial (AM) domains directs the distribution of glands at the AM domain (Goad et al., 2017). Additional evidence shows that glands opening into the lumen secrete LIF under the regulation of FoxA2, which is essential for implantation in mice (Kelleher et al., 2017).

Molecular and cellular changes occur early in pregnancy to prepare the uterus for implantation (receptive phase). With the acquisition of blastocyst competency in the receptive uterus, implantation ensues (Dey et al., 2004). This “window of implantation” is a time-sensitive transient period when blastocyst competency coincides with the receptive state of the uterus on specific day(s) of pregnancy. When this coordination falls out of phase, implantation fails or becomes defective and generates adverse ripple effects throughout the course of pregnancy, leading to a poor pregnancy outcome (Song et al., 2002; Cha et al., 2012). The receptive window for implantation is also thought to be transient in humans; implantation past this window can lead to spontaneous miscarriages (Wilcox et al., 1999). In humans, the natural rate of conception per cycle (~30%), and up to 75% of failed pregnancies seem to be due to implantation failure (Norwitz et al., 2001). However, a significant number of miscarriages result from abnormal embryo development due to aneuploidy (reviewed in (Cha et al., 2012).

Implantation Stages and Types

Embryo implantation was historically dubbed “nidation” which originates from the word “nidus”, meaning a nest or breeding place. It is the first cooperative physical and physiological interaction between the epithelium (trophectoderm) of the blastocyst and the maternal endometrial lining (luminal epithelium). The prerequisites for mammalian embryo implantation include preimplantation embryo development and blastocyst competency for implantation, differentiation of the uterus to a receptive state, formation of uterine crypts (implantation chambers) and attachment of the blastocyst with the luminal epithelium. These events are the result of a reciprocal blastocyst-uterine dialogue (Lim and Wang, 2010; Cha et al., 2012). In mice and rats, initiation of implantation occurs on the evening of day 4 (day 1 = morning of finding vaginal plug) or day 5 of pregnancy (day 1 = sperm in vaginal smears), respectively. One of the early signs of implantation in many species is a local increase in vascular permeability at the site of blastocyst apposition, which can be monitored by an intravenous injection of a macromolecular blue dye that binds to serum proteins and leaks out at sites of increased vascular permeability; this process demarcates the implantation sites as distinct blue bands (Psychoyos, 1973). Following implantation, the underlying stromal cells proliferate and differentiate to decidual cells (decidualization) accompanied by marked matrix remodeling and angiogenesis to establish communications between the nascent vascular system of the conceptus and mother to form the presumptive placenta (Cha et al., 2012).

Enders and Schlafke characterized implantation as occurring in three discrete stages: apposition, adhesion, and penetration (Enders and Schlafke, 1969). During apposition, the blastocyst trophoctoderm becomes closely apposed to the uterine luminal epithelium (LE). When this intimate association is sufficient to resist dislocation of the blastocyst upon flushing the uterine lumen, implantation has progressed to the adhesion stage. Penetration is then associated with the breaching of LE by the trophoctoderm. By this stage, decidualization of underlying stromal cells progresses with extensive loss of the epithelial cells.

The entry of trophoblast cells into the stroma with the advancement of implantation was thought to be mediated by epithelial apoptosis. However, recent studies in mice have provided evidence that epithelial cells in contact with the blastocyst are engulfed by trophoctoderm cells by a nonapoptotic, cell-in-cell internalization process called entosis (Li et al., 2015). This process, which has

been previously characterized in cancer, was shown to have a physiologic role in normal pregnancy. However, the molecular mechanism behind this process is yet to be defined.

Implantation strategies vary between species and have been classified on the basis of divergent cell-cell interactions between the blastocyst and uterus. Bonnet classified implantation into three categories: central, eccentric and interstitial (Bonnet, 1884). Central implantation, observed in rabbits, ferrets, and some marsupials, occurs when blastocysts extensively expand prior to implantation to be closely apposed and maximally interact with the LE. In contrast, blastocysts in mice, rats, and hamsters show only modest expansion and undergo eccentric implantation, during which implantation chambers are formed within evaginations from the uterine lumen. Notably in rodents, implantation always occurs at the anti-mesometrial (AM) domain of the uterus, opposite to the mesometrial (M) domain, the entry site of blood vessels into the uterus (see below: **Uterine Changes in Implantation**). In contrast, implantation occurs at the mesometrial site in bats. Interestingly, during interstitial implantation observed in guinea pigs, chimpanzees and humans, blastocysts implant by entrenching into the subepithelial stroma (Dey et al., 2004).

Schlafke and Enders further classified implantation types as intrusive, displacement and fusion based on the results of ultra-structural electron microscopy studies (Schlafke and Enders, 1975). During intrusive types of implantation, which is seen in humans and guinea pigs, trophoblast cells penetrate through the LE to reach the basal lamina. In displacement type of implantation which occurs in rodents, the basal lamina disassociates from the overlying LE to facilitate trophoblast invasion into the subepithelial stromal bed. In contrast, rabbits exhibit fusion type of implantation in which trophoblast cells fuse with the LE by forming symplasma (trophoblastic knob, the syncytial aggregates that attach to and invade the endometrium) (Schlafke and Enders, 1975). In rabbits, attachment stimulates an angiogenic response, particularly at the trophoblastic knobs, the syncytial aggregates that attach to and invade the endometrium with increased expression of vascular endothelial growth factor (Das et al., 1997).

Noninvasive implantation has been observed in large animals and marsupials, such as the pig, sheep, cow, horse, and wallaby (Renfree and Shaw, 2000; Roberts et al., 2008; Bazer, 2015). For example, pig blastocysts remain in a “free-floating” state with noninvasive implantation until day 12 (termed pregnancy recognition) at which point it elongates up to 100 mm in length, primarily due to the rapid growth of the extraembryonic tissue. This strategy allows an efficient nutrient and metabolite exchanges between the uterus and conceptus until the attachment reaction.

Uterine Changes During Implantation

Corner once remarked: “the uterine chamber is actually a less favorable place for early embryos to implant than say, the anterior chamber of the eye, except when the hormones of the ovary act upon it and change it into a place of superior efficiency for its new functions” (Corner, 1947). The differentiation of the uterus to a receptive state during pregnancy that renders it favorable for the implantation and development of an embryo was first described by Alexandre Psychoyos. By reciprocal embryo transfer experiments using pseudopregnant and delayed-implanting rodent models, he established the concept of the transient window of receptivity by showing that blastocysts only implanted when transferred into a hormonally prepared, receptive uterus (Psychoyos, 1973). It was found that blastocysts implantation in uteri of mice or rats requires at least 24–48 h of P₄ priming superimposed with a small amount of estrogen (Psychoyos, 1973). Later, reciprocal blastocyst transfer experiments showed that the acquisition of blastocyst activation and uterine receptivity for implantation both require in vivo exposure to estrogen (Paria et al., 1993). Thus far, all mammals studied exhibit a transient window of uterine receptivity of varying duration for implantation (Cha et al., 2012; Yoshinaga, 2013).

Although both P₄ and estrogen are essential for implantation in mice and rats, ovarian estrogen is not a requirement for implantation in hamsters, rabbits and pigs. Blastocysts can implant in these species only in the presence of P₄; surprisingly, neither P₄ nor estrogen is required for implantation in guinea pigs (Deanesly, 1963). It was conjectured that embryos in these species can locally produce the steroid hormones required for implantation. Indeed, biochemical experiments provided evidence that the rabbit and pig blastocysts have the capacity to synthesize estrogens (Perry et al., 1973; Hoversland et al., 1982); this capacity was not found in mouse blastocysts (Stromstedt et al., 1996).

The acquisition of uterine receptivity in preparation for blastocyst attachment is reflected in both cellular and molecular changes involving the three major uterine compartments (epithelium, stroma, and myometrium) uniquely responding to changing ovarian P₄ and estrogen secretion. To create the window of uterine receptivity, the cooperative interactions between P₄ and estrogen regulate uterine cell proliferation and/or differentiation in a spatiotemporal manner in mice and rats. In rodents and humans, there is a gradual loss of apicobasal LE cell polarity and formation of microprotrusions called pinopodes or uterodomes on the apical surface of the LE impending blastocyst attachment (Thie et al., 1996; Nikas and Psychoyos, 1997).

Along the same vein, the epithelial apico-basal cell polarity is considered critical to implantation. In the search for the molecular mechanism underpinning this event, muscle-segment homeobox genes *Msx1* and *Msx2* were found to play a major role in modulating apico-basal polarity and implantation by altering uterine *Wnt5a* levels (Daikoku et al., 2011). MSX transcription factors are also important for regulating delayed implantation in the mouse, tammar wallaby and North American mink (Cha et al., 2013b). The molecular aspects of embryo competency and uterine receptivity are described in separate chapters.

Blood vessels travel to the uterus through the mesometrium and anatomically orient the uterus into mesometrial and anti-mesometrial domains (Cha et al., 2012). In rodents, embryo homing and implantation occur within a crypt (implantation

chamber) invariably at the AM domain along the uterus. On day four of pregnancy in mice (day 1 = vaginal plug), epithelial evaginations (folding) project from the uterine lumen toward the AM domain. A certain number of projections provokes blastocysts to form crypts for embryo implantation. The unique architectural organization of crypts for blastocyst homing and attachment was first recognized in rodents more than a century ago (Burckhard, 1901) and later by Enders' group (Enders et al., 1980). However, the mechanism by which epithelial evaginations are appropriately directed to form crypts at the AM domain for embryo homing and implantation remained unknown. It also remains undefined how the crypts homing the embryos are regularly spaced.

Recent studies show that crypt formation at the AM domain requires non-canonical Wnt5a-ROR signaling. Epithelial projections form along a *Wnt5a* expression gradient, and mice with disruption of uterine Wnt5a-ROR signaling with conditional uterine loss or gain of function of *Wnt5a* or loss of function of *Ror1/Ror2* (*Wnt5a* co-receptors) resulted in disorderly epithelial projections, crypt formation, embryo spacing, and impaired implantation (Cha et al., 2014). These early disturbances under abnormal Wnt5a-ROR signaling were reflected in adverse late pregnancy events (Cha et al., 2014). Further studies showed that Wnt5a-ROR signaling intersects planar cell polarity (PCP) signaling orchestrating the formation of directed epithelial evaginations to form crypts for implantation in mice (Yuan et al., 2016).

PCP is a developmental pathway essential for establishing spatial cues in multicellular tissues during organogenesis and branching morphogenesis during mammary gland development (Yang and Mlodzik, 2015). In animal models, disrupting PCP signaling genetically or pharmacologically results in abnormal hair cell orientation, giving rise to defects in neural tube closure and left-right asymmetry; in humans, polymorphisms of PCP components are associated with an array of developmental defects including spina bifida and cardiac outflow malformations (van Amerongen and Nusse, 2009). While PCP has been studied extensively during development, its role in adult tissues in physiological conditions has been limited. Recent studies show that uterine deletion of Vang-like protein 2 (*Vangl2*), but not *Vangl1*, confers aberrant PCP signaling, misdirected epithelial evaginations, defective crypt formation, and blastocyst attachment, leading to compromised pregnancy outcomes (Yuan et al., 2016). The study identified a novel role for PCP in executing spatial cues for crypt formation and implantation (Fig. 1).

PCP signaling is evolutionarily conserved, although it is not known whether uterine PCP activity is important for implantation across species including humans. Additional studies have shown that the correct orientation of the embryonic axis within the crypt is also critical for pregnancy success in mice (Zhang et al., 2014); Notch signaling was determined to be a key component.

Fig. 1 A schematic diagram of PCP signaling pathway in designing epithelial evagination and crypt formation for embryo implantation at the AM domain of the uterus. As the downstream signaling of Wnt5a-ROR, *Vangl2* directly interacts with *Scrib*, *Celsr1*, and *Dvl2* to form a complex to maintain epithelium planar polarity. After blastocyst attachment within the crypt epithelium, an opposing balance between *Noggin* and *Bmp2* signaling in the subepithelial stroma facilitates the progression of implantation and decidualization. Right panel shows Wnt5a-ROR-PCP signaling regulates the luminal epithelium to form a “conch-shaped” crypt to home the embryo (normal implantation). Left panel shows defective implantation in a roundish crypt due to aberrant PCP signaling. M, mesometrium; AM, antimesometrium; BV, blood vessel; GE, glandular epithelium; LE, luminal epithelium.

Defective Implantation and Decidualization Causes Adverse Ripple Effects

Despite scientific advances in human fertility by assisted reproductive technologies, the implantation rate and number of ‘take-home’ babies still remain low (Norwitz et al., 2001). Poor embryo quality, transfer of embryos into uteri of unknown states of receptivity, and complications from inferior quality of implantation are all barriers to successful pregnancy. Indeed, defective implantation was shown to propagate adverse ripple effects throughout the remainder of pregnancy, resulting in compromised pregnancy outcomes, including preterm birth and preeclampsia which can have life-long health effects on the offspring.

Mouse models have helped to define propagation of early defects through the remaining course of pregnancy. The first study of adverse ripple effects from defective implantation was noted in mice deficient in *Pla2g4a* (encoding cPLA 2α), which generates arachidonic acid from membrane phospholipids for prostaglandin synthesis via COX enzymes. Implantation in *Pla2g4a* $-/-$ mice occurs beyond the normal window of implantation (deferred implantation), resulting in embryo crowding, conjoined placenta, arrested fetoplacental development, increased resorptions and reduced litter size (Song et al., 2002). The authors also performed proof-of-principle physiological experiments in which blastocysts were transferred to wild-type mouse uteri beyond the anticipated window of uterine receptivity and showed similar adverse phenotypes of reduced litter size and increased resorption. Finally, similar findings were observed for mice deficient in *Lpar3* (LPA3), a receptor for lysophosphatidic acid (Ye et al., 2005). The similar phenotypes were attributed to reduced production of prostaglandins generated by COX2, implicating a LPA3-cPLA 2 -Cox2 signaling axis as a critical determinant for on-time implantation.

Preeclampsia is believed to result from abnormal placentation. A recent study in a mouse model which spontaneously develops the cardinal features of preeclampsia showed periimplantation defects including upregulation of Cox2 and IL-15 at the maternal-fetal interface (Sones et al., 2016). This was associated with decreased decidual natural killer (dNK) cells, which have important roles in placental perfusion. A single administration of a Cox2 inhibitor (celecoxib) during decidualization restrained Cox2 activity and IL-15 expression, restored dNK cell numbers, improved fetal growth, and attenuated late gestational hypertension. This study provides evidence that decidual overexpression of Cox2 and IL-15 may trigger the adverse pregnancy outcome reflected in the preeclampsia syndrome.

Aberrant decidualization can also give rise to adverse pregnancy phenotypes including aberrations in parturition. Preterm birth is one example of an adverse pregnancy effect of defective decidualization. The Dey lab has shown that mice with uterine deletion of *Trp53* (encoding p53; *Trp53*^{d/d}) show normal implantation, however, 50–60% of *Trp53*^{d/d} mice exhibit preterm birth with dystocia and fetal death (Hirota et al., 2010). These mice have compromised decidualization with more terminally differentiated decidual cells than control littermates with increased polyploidy, senescence-associated growth restriction, and heightened expression of pAkt, p21 and Cox2. Many risk factors, such as genetic mutation, infection, inflammation and stress that lead to preterm birth are also reported to exacerbate cellular senescence via mammalian target of rapamycin complex 1 (mTORC1) signaling. Rapamycin attenuates senescence and increase life span in mice (Harrison et al., 2009). *Trp53*^{d/d} decidua have increased mTORC1 activity, which is inhibited by rapamycin or metformin with attenuation of premature decidual senescence and rescue of preterm birth (Hirota et al., 2010; Cha et al., 2013a). This finding is intriguing since women of advanced age exhibit higher rates of preterm birth (Cnattingius et al., 1992) and a cohort of Japanese women who delivered preterm showed increased decidual senescence compared to term counterparts (Cha et al., 2013a). These results are a paradigm shift in our understanding of the physiology of birth timing and pathogenesis of preterm birth by identifying a decidual origin of preterm birth which can be targeted using mTORC1 inhibitors (Fig. 2). Whether this intervention can be applied broadly remains to be studied; clinical research to study decidual senescence in women with higher risk factors for preterm birth will be useful to target this global problem.

In this regard, higher levels of endocannabinoid signaling have also been shown to enhance preterm birth in response to a mild inflammatory stimulus. Increased p38/MAPK independent of mTORC1 signaling accelerates decidual senescence (Sun et al., 2016), suggesting that decidual senescence may function as a common final pathway integrating multiple signaling pathways toward birth timing.

Future Considerations

With marked advances in technology, much remains to be revealed about the dynamic physiological and molecular interactions encompassing early pregnancy events. The precise timing of implantation and the molecular discourse between the embryo and uterus have yet to be determined in humans. Already, advances in high fidelity RNA-Seq and MALDI-MS proteomics have helped to identify low-abundance molecular and modified mediators not previously noted. Recent application of in situ mass spectrometry in periimplantation mouse uteri also provide opportunities to generate spatiotemporal maps of proteins and lipids as well as their modifications in other species including humans (Burnum et al., 2009). Furthermore, analysis of the single cell transcriptome of human preimplantation embryos and the epigenetic signature of primordial germ cells has opened new avenues to map the transcriptome of single epithelial and stromal cells in the uterus around the time of implantation (Yan et al., 2013; Guo et al., 2015; Petropoulos et al., 2016). These datasets coupled with those from MALDI-MS proteomics and lipidomics profiles can be used to

Fig. 2 A scheme showing that defective decidualization leads to preterm birth. Decidual senescence caused by genetic predisposition due to gene mutation superimposed by mild inflammation confers compromised decidual health and increased susceptibility to preterm birth. Heightened mTORC1 signaling is a signature of premature decidual. Signaling by p53-Sesn2 dampens mTORC1 signaling which is further helped by Met and Rsv through increased AMPK signaling in the context of inflammatory insult.

identify mediators secreted by embryos freely or in exosomes and their downstream effects that can promote their own growth or signal the endometrium for implantation.

Epigenetic regulation allows for versatile and reversible changes in gene expression without changing the underlying DNA sequence. New insights on epigenetic regulation of reproductive events continue to be gleaned, including the roles of histone modifications, chromatin remodeling, DNA methylation, microRNA and long noncoding RNAs (lncRNA), and novel transcription factor response elements such as the super enhancer identification (Pott and Lieb, 2015; Dekker and Mirny, 2016). The signature of estrogen and progesterone receptors binding sites and their downstream mediators have been assessed by genome-wide assays and are likely to have a substantial impact on implantation and pregnancy events (Pott and Lieb, 2015; Rubel et al., 2016; Vasquez et al., 2016). There is evidence regarding the roles of histone modifications in reproduction, especially the roles of the Polycomb repressive complexes 1 and 2 (PRC1 and PRC2) which are distinguishable by their core components. PRC1 components, including the E3 protein ligases responsible for ubiquitination of histone H2A, Ring1A and Ring1B, (Margueron and Reinberg, 2011) and chromobox (CBX) family (Schwartz and Pirrotta, 2013) are differentially and spatiotemporally expressed in the periimplantation uteri. Notably, inhibition of PRC1 activity by a Ring1A/B inhibitor compromises decidualization and polyploidy development during early pregnancy in vivo, while interference of Cbx4 expression in stromal cells also show defective stromal cell decidualization and polyploidy development in vitro (Bian et al., 2016). During decidualization and decidual polyploidy, DNA methylation was shown to be important in hormone-dependent gene expression in the pregnant uterus (Gao et al., 2015). H3K27 methyltransferase activity by PRC2 is relayed by its component proteins including EZH1/EZH2, SUZ12 polycomb repressive complex 2 subunit (SUZ12) and RB binding protein 7 (RBAP46) or RB binding protein 4 (RBAP48) (Blackledge et al., 2015). The increased H3K27me3 at the promoter of chemokine (C–C motif) ligand 8 (CCL8) and chemokine (C–C motif) ligand 9 (CCL9), critical chemokines for T cell migration from stroma to myometrium, confers a local immune-privileged region for embryo development, indicating the importance of this epigenetic mark in pregnancy (Nancy et al., 2012). Finally, EZH2 has dynamic expression during the menstrual cycle in humans and is suppressed in decidualized stromal cells, implicating a role for EZH2-PRC2 mediated chromatin remodeling in the human endometrium (Grimaldi et al., 2012). The role of these epigenetic marks in pregnancy events remains to be validated in a physiological setting. The novel Crispr-Cas9 system will provide an efficient way to systematically isolate the function of these targets in mammalian systems (Hsu et al., 2014; Gorski et al., 2017). Progress in precisely defining the molecular window of implantation and identifying regulators of dynamic embryo-uterine interactions will continue in stride with refined technological tools. These evolving areas of research warrant careful investigation in animal models which can then be expanded to human studies.

Functions of the Mammalian Uterus

The mammalian uterus plays a large number of critical roles in reproduction. The most familiar of these is that the uterus is the site of fetal growth and development, but the uterus has extensive other functions in reproduction as well. The uterine cervix has a key barrier function in inhibiting passage of bacteria or other infectious agents into the uterus, but under appropriate hormonal conditions allows and even facilitates sperm passage from the vagina into the uterus. Although semen is deposited in the vagina near the cervix in humans, the uterus is the site of semen deposition in a number of species such as the pig, horse and dog. The uterine environment is crucial for sperm capacitation, and uterine peristaltic contractions following semen deposition help move sperm toward the oocyte.

Following fertilization, the uterus nourishes and maintains the embryo until implantation and placentation, typically by the secretions of uterine glands. In some species, such as mice, embryos spend only a short period of time in the uterus before implantation, which occurs shortly after fertilization. In humans, implantation occurs about 9 days after fertilization, and since the embryo spends a few days in the oviduct before entering the uterus, the time that the embryo spends unattached in the uterus is fairly limited. In contrast, in species like cattle, embryo implantation does not occur until more than 3 weeks post-fertilization (Blomberg et al., 2008), and the bovine embryo is dependent on nutrition from the uterus for a significant amount of time before implantation.

A more extreme example of the uterus sustaining embryos for extended periods is the phenomenon known as delayed implantation or embryonic diapause, which has been reported in over 100 mammalian species. In some species that have delayed implantation, such as the tammar wallaby, nine-banded armadillo and western spotted skunk, embryos develop up to the blastocyst stage and then remain semi-dormant in the uterus for months. Furthermore, under experimental conditions, intrauterine embryos can remain unattached but viable in the uterus for up to 2 years before implantation, and the uterus sustains the embryo during this time. Entry into embryonic diapause can be induced as a result of lactation and/or seasonal factors, depending on the specific species, with some species such as the tammar wallaby showing both lactationally and seasonally controlled diapause.

The uterine wall is the site of embryo implantation, and this process is a complex and intricately regulated one that shows extensive species variation and must occur normally to allow embryonic development. The uterus is also where placentation occurs. Placentation differs markedly in various mammalian species. In some species (e.g., mice, humans), the blastocyst invades into the endometrium and disappears from the lumen, while in other species (e.g., cattle) the fetus remains on the luminal surface of the uterus and the fetal portion of the placenta develops in close apposition to the uterine epithelium but does not invade through it. Thus, the uterus plays a critical role in placentation and fetal development.

Lastly, the uterus plays an essential role in parturition. When considering parturition in elephants, where a newborn may weigh up to 120 kg, or in a giraffe where a newborn may be 1.9 m tall, the enormity of delivering a mature fetus from the intrauterine environment into the outside world while not injuring the fetus or otherwise compromising fetal/newborn respiration becomes clearer.

Uterine Anatomy in Mammals

In most mammals, the uterus has three distinct segments: cervix, body and horns. Although uterine morphology varies significantly amongst species, both histological structure and function are highly conserved. Humans possess a *simplex uterus* lacking uterine horns and composed of the body compartment and cervix. Rodents, rabbits and marsupials have a *duplex uterus* with separate uterine horns. Rodents such as rats and mice have cervixes that branch into each uterine horn compartment, while rabbits, hares, and marsupials possess two individual cervical canals. The *bicornuate uterus* is the most prevalent type of mammalian uterus and is characterized by two distinct horns, and a uterine body. Polytocous species such as the pig, dog and cat possess relatively large horns with a smaller body, while monotocous species (e.g., cattle and horse) have less developed horns.

Similar to other tubular organs, uterine histoarchitecture (Fig. 1B) consists of four circular tissue layers called tunics (mucosa, submucosa, muscularis and adventitia/serosa) surrounding a central uterine lumen. However, in general, the uterus is divided into three layers; *endometrium* (mucosa and submucosa), *myometrium* (muscularis) and *perimetrium* (adventitia/serosa).

The endometrial mucosa is lined by a cuboidal to columnar luminal epithelium (LE). The connective tissue layer immediately below the LE is the lamina propria. During uterine development (Fig. 1A), the uterus initially consists of an undifferentiated mesenchyme surrounding a central single-layered LE. The proliferating LE give rise to glandular epithelium (GE) that invaginates into the submucosa and forms simple or branched coiled tubular uterine glands, depending on the species (Cooke et al., 2013). In mice, uterine glands are spatially arranged in lateral to anti-mesometrial regions (opposite side of the broad ligament) of the uterus as a result of active Wnt signaling being limited to the anti-mesometrial region, and consequently implantation typically occurs anti-mesometrially (Goad et al., 2017). However, it is unclear whether this phenomenon occurs in other species. Below the mucosa,

Fig. 1 Schematic representation of cross-sections of adult and developing uterus. Panel A represents the undifferentiated neonatal rodent uterus, which consists of a single layer of luminal epithelium (LE) surrounded by undifferentiated mesenchymal cells (M). The adult uterus consists of endometrial, myometrial, and perimetrial layers. Panel B shows a high-power view of cell–cell interactions that are critical for progesterone (P4) response and decidualization. P4 stimulates Indian Hedgehog (IHH) expression through progesterone receptors (PR). Production of IHH by LE promotes decidualization of neighboring stromal cells (Str) through COUP-TFII signaling. Panel C diagrams proliferation and implantation pathways regulated by steroid hormones. 17 β -Estradiol (E2) acts through estrogen receptor 1 (ESR1) in the stromal cells to promote secretion of various members of the fibroblast growth factor family (FGFs). This stromally-derived FGF acts on adjacent epithelial cells through FGF receptor, inducing cellular proliferation. High concentrations of P4 at the time of implantation act through PR in the stromal cells to induce the production of HAND2, which inhibits secretion of FGFs from the stromal compartment and thus blocks epithelial proliferation. In addition to effects on stromal FGFs, E2 also acts through ER in glandular epithelium (GE) to induce expression of leukemia inhibitory factor (LIF). The LIF produced in the GE then acts on LIF receptors (LIFR) in the LE to activate epithelial STAT3. This leads to the production of a number of EGF-family ligands (EGF), which act on stromal EGF receptors (EGFR) to promote implantation.

fibroblasts, blood vessels, lymphatics, nerves, white blood cells and type III collagen make up the stroma located between the LE and GE.

Although general endometrial structure is similar, there are species differences. The ruminant endometrium has specialized protuberances called caruncles, which are highly vascularized non-glandular structures that contribute to maternal side of the placenta. The endometrium of mares and sows is highly folded compared to other species. In primates, the endometrium is further divided into the basalis and functionalis regions (**Fig. 2**), the latter of which thickens during the cycle and then sloughs off during menstruation.

The adult uterine myometrium has two smooth muscle layers, an inner circular and outer longitudinal layer, separated by connective tissue. Myometrial contraction helps move the uterine contents either toward the oviduct during estrus/fertilization or the cervix during parturition. Estrogens increase myometrial tone or degree of contraction while progesterone decreases the tone. During pregnancy, the myometrium undergoes major remodeling and is responsible for the majority of the increase in uterine weight through myometrial hyperplasia and hypertrophy, and collagen deposition. After parturition, uterine involution is marked by myometrial involution resulting from cell death, hypotrophy and enzymatic degradation of collagen.

The perimetrium consists of a thin layer of squamous epithelium that is continuous with the serosal layer of the peritoneum and broad ligament of the uterus. The broad ligament houses blood vessels, lymphatics and nerves that supply the uterus.

The uterus is a dynamic organ that undergoes sequential remodeling during different phases of the estrous or menstrual cycle, and during pregnancy and after parturition. There is evidence that stem cells for each uterine cell type are a source of LE, GE, stroma and myometrial cells that are lost during remodeling (**Teixeira et al., 2008**). In addition, bone marrow-derived stem cells are capable of contributing to uterine repair after injury, and these stem cells may have clinical benefit in certain conditions such as Asherman's

Fig. 2 Schematic diagram of cyclic changes in human uterine histology during the menstrual cycle. The menstrual phase begins with onset of bleeding and lasts for about 4 days. In the absence of pregnancy, the ovarian corpus luteum undergoes luteolysis, resulting in a rapid decline in P4 that results in local inflammation and tissue breakdown and shedding of the functional layer of the endometrium. By late menses, the endometrium consists of only the basal layer. The proliferative phase (follicular phase) lasts for an average of 10 days and coincides with a gradual increase in serum E2 produced by developing follicles. This phase is characterized by increased proliferation of glandular and luminal epithelium under the influence of E2, which reconstitutes the functional endometrium. Glands at this stage are simple tubular and have narrow lumens. The secretory phase (luteal phase) lasts about 14 days, and starts after the ovulation. This phase is marked by rising progesterone secretion from the corpus luteum and a sudden fall in E2 concentrations. Under the influence of progesterone, endometrium grows further and reaches maximal thickness. Glands become highly coiled and dilated with secretory products. During this phase, the endometrium is edematous and shows little cell proliferation. If pregnancy is not established during the secretory phase, progesterone concentrations fall and the shedding of the functional layer begins the next menstrual cycle.

syndrome (Sahin Ersoy et al., 2017), which is characterized by uterine fibrosis and adhesions. It is hypothesized that uterine stem cells also play a role in pathogenesis of uterine fibroids and cancer (Teixeira et al., 2008).

Uterine Development

In females, the Müllerian (paramesonephric) ducts present in both sexes during the ambisexual stage develop into the uterus, oviduct and cranial portion of the vagina. The area of fusion of the two bilateral Mullerian ducts produces the uterine body, while unfused regions give rise to uterine horns. A functional adult uterus, capable of sustaining successful pregnancy, is established through biphasic postnatal growth and differentiation during the pre-pubertal and post-pubertal periods. At birth, the uterus is a simple tube consisting of epithelium and mesenchyme in rodents (Fig. 1B). However, in other domestic animals, the uterus is already radially patterned into epithelium, stroma and myometrium at birth (Cooke et al., 2013). In contrast, human uterine architecture at birth is similar to adults due to exposure to maternal hormones (Gray et al., 2001). After birth, the uterus remains quiescent during early childhood years. Around puberty in humans, the uterus starts to grow and uterine endometrium begins to proliferate and assumes the adult uterine structure. In all species, including humans, continued postnatal uterine development and morphogenesis into functional endometrium with glands and myometrium from birth to puberty is crucial for adult function. The uterus attains its adult histo-architecture by 2 weeks of age in rodents, and by 2–3 months in sheep and pig. These observed temporal differences between species in postnatal uterine development and histo-architecture are attributed to the degree of maturity at the time of birth and the maternal hormonal milieu during gestation.

The exact mechanisms or signaling pathways that govern Müllerian duct development and regulate the differentiation of the various organs derived from this fetal structure are not completely understood. Recent seminal work by Nakajima et al. (2016) has demonstrated that retinoic acid signaling is critical for initiating the unique sequence of uterine development from the multipotent Mullerian duct. In addition, many genes are known to be necessary for normal uterine development, and mutations of genes such as PAX2, LIM1, Emx2, Wnt4, Wnt9b and other members of the WNT gene family of secreted signaling molecules results in Müllerian duct agenesis or impaired uterine development [reviewed in (Teixeira et al., 2008)].

As the uterus differentiates, mesenchyme surrounding the LE differentiates into the stroma and two myometrial layers. The mechanisms regulating this are unclear, but epithelium is required for normal development and differentiation of uterine myometrium, as well as stroma, as described in detail subsequently in this chapter. Thus, reciprocal communication between

epithelium and mesenchyme is essential for normal uterine differentiation and morphogenesis in rodents (Kurita et al., 2001).

In mice, higher rates of cell proliferation during the early neonatal (pre-pubertal) and post-pubertal period (Nanjappa et al., 2015) are major contributors to the size of the adult organ. Somewhat surprisingly, pre-pubertal uterine development in mice occurs normally in the absence of endogenous 17 β -estradiol (E2) and progesterone (P4), even though the neonatal uterus expresses steroid receptors [estrogen receptor 1 (ESR1), estrogen receptor (ESR2), G protein-coupled estrogen receptor 1 (GPER) and progesterone receptor (PR)] and responds to exogenous E2 or P4 (Hewitt et al., 2016). Signaling molecules that drive pre-pubertal uterine cell proliferation and development are not completely elucidated, although growth factors may play a role. However, for normal post-pubertal uterine growth and functions, E2 and P4 actions through their receptors are required (Hewitt et al., 2016).

Regulation of Endometrial Gland Development

Uterine glands are formed from the proliferating LE that differentiate into GE and form invaginations into the submucosa. In contrast to humans, uterine glands development (adenogenesis) occurs after birth in most domestic species and rodents. Uterine glands are formed around 20–22 weeks of gestation in humans. Adenogenesis begins in the first postnatal week of life and is completed by about day 15 postnatal in rodents, and day 56 and day 120 in sheep and pig, respectively (Gray et al., 2001). In mice, uterine glands are relatively simple tubes with limited branching, while in other species such as sheep and pig, uterine glands are tightly coiled and highly branched tubular glands (Goad et al., 2017).

Mechanisms that regulate adenogenesis are unclear, but cell–cell and cell–ECM interactions and stromally-derived factors influence adenogenesis (Gray et al., 2001). Several genes have been linked to uterine gland development in mice, such as the Wnt gene family (Wnt4, Wnt7a, Wnt5a, Wnt11, Wnt16) and their receptors (Fzd6 and Fzd10), Beta-catenin 1, Hoxa10, Hoxa11, Lef1 Vangl2 and Cdh1 [reviewed in (Cooke et al., 2013; Goad et al., 2017)].

Development of a functional adult uterus capable of sustaining and allowing early conceptus survival, implantation and decidualization requires initial adenogenesis during the pre-pubertal and post-pubertal period. Thus, impaired adenogenesis during the critical window of normal development has long-term consequences and cause infertility in adults. Exposure to hormones such as P4 during adenogenesis delays or completely prevents formation of glands in the adult uterus and causes infertility (Gray et al., 2001; Cooke et al., 2013). However, neonatal ovariectomy or inactivating mutations in major receptors of steroid hormones (e.g., ESR1, ESR2, PR) do not prevent neonatal or pre-pubertal adenogenesis. Once glands are established during the neonatal/pre-pubertal period, post-pubertal gland maintenance and further development are primarily dependent on the E2/ESR1 signaling (Nanjappa et al., 2015). Thus, uterine differentiation and adenogenesis during the pre-pubertal and post-pubertal periods are essential for normal fertility in adults.

Estrous Vs. Menstrual Cycle

Beginning at puberty, females begin to show reproductive cycles, although the length and features of these cycles varies amongst species. In the uterus, hormonal changes during the cycle induce functional and architectural changes in preparation for implantation of a fertilized egg and subsequent gestation (Fig. 2). All these events are intricately orchestrated, and if embryonic implantation does not occur the uterine endometrium either sheds in species that undergo a menstrual cycle or regresses in species with estrous cycles. Menstrual cycles are characteristic of primates (Fig. 2), but have also been observed in mammals such as elephant shrews and several families of bats [reviewed in (Emera et al., 2012)]. In the absence of pregnancy in primates, declining progesterone causes local inflammation and tissue breakdown and shedding of the upper two-thirds of the endometrium during the menstrual phase of the cycle (Maybin and Critchley, 2015). The non-primate mammals that have a menstrual cycle exhibit endometrial growth and differentiation during the cycle and also expel endometrial epithelial necrotic debris and erythrocytes if pregnancy does not occur, analogous to menses in primates.

The estrous cycles of placental mammals can be classified according to their frequency throughout the year. Monoestrous species such as wolves, foxes and bears have one cycle per year, while seasonally polyestrous animals such as horses, sheep and goats cycle multiple times during specific seasons of the year. Both monoestrous and seasonally polyestrous species have evolved to allow birth of offspring when environmental conditions are most favorable for their offspring. Lastly, rodents, cows and pigs are polyestrous and cycle regularly through the year.

Uterine remodeling and proliferation occurs in waves during different stages of the cycle, and these changes are mediated by E2 and P4. Ovaries are the major site of E2 and P4 synthesis, and concentrations of these hormones vary in concert with ovarian changes during the cycle. Systemic concentrations of E2 rise during the follicular phase of the cycle, as the ovary contains one or more dominant follicles developing for ovulation. The actions of E2 and other signaling molecules prepare reproductive organs for estrus and fertilization by inducing a wide array of processes, including uterine LE and GE proliferation. After ovulation, the corpus luteum is formed in the ovary, leading to rising systemic P4 concentrations. Progesterone induces uterine stromal differentiation and proliferation, and inhibits E2-induced LE and GE proliferation. Additionally, P4 plays a fundamental role in the decidualization process of estrogen-primed fibroblast cells in the uterine stroma necessary for pregnancy establishment [Reviewed in (Dunn et al., 2003)].

Uterine Hormonal Responses Involve Reciprocal Epithelial–Connective Tissue Communication

As described above, the uterus is a major target of estrogen and progesterone signaling, and ESR1, ESR2, GPER and PR are abundant in this organ. Expression of ESR1 and PR, for example, occurs in all epithelial cells and the vast majority of mouse uterine stromal cells. Estrogens are the major regulator of uterine epithelial development and function, and epithelial proliferation, secretory protein production and height are all estrogen-regulated. Progesterone blocks mitogenic estrogen effects and other estrogen-stimulated processes in uterine epithelium. Given the high uterine epithelial ESR1 expression and the critical estrogen roles in uterine epithelial function, it seems obvious that estrogens must induce processes such as epithelial proliferation directly through epithelial ESR1. Similarly, progesterone inhibition of mitogenic estrogen effects on uterine epithelial proliferation would logically occur directly through epithelial PR. However, over the past 4 decades, it has become clear that stimulatory and inhibitory effects of E2 and P4, respectively, on uterine epithelial proliferation are mediated indirectly through effects on connective tissue steroid hormone receptors.

Extensive research extending back to pioneering studies of the German embryologist Hans Spemann in the early 20th century established that connective tissue controls initial differentiation, proliferation, patterning and function of epithelial cells in developing organs. Work in the 1980s examining estrogen responses in neonatal mice suggested that connective tissue might also control epithelial response to estrogen in female reproductive organs, and estrogen effects on endpoints such as uterine epithelial proliferation might be mediated indirectly through the connective tissue. Neonatal mice express ESR1 in uterine mesenchyme, the undifferentiated connective tissue that is the precursor of the stroma, but not in the epithelium. Despite this, estrogen treatment of these mice induced robust increases in epithelial proliferation, and epithelial ESR1 was not detectable even after estrogen stimulation (Bigsby and Cunha, 1986). This suggested that mesenchymal ESR1 could mediate mitogenic estrogen effects on uterine epithelial proliferation, potentially analogous to the situation in males where androgen stimulation of epithelial proliferation in organs such as the prostate is indirect through connective tissue. However, concerns that neonatal uterine epithelium might express estrogen receptor in amounts sufficient to mediate estrogen-induced epithelial proliferation but insufficient to be detected by the techniques then in use for analyzing estrogen receptor expression made it impossible to definitively conclude that estrogen stimulation of uterine epithelial proliferation was mediated indirectly.

Estrogen Effects on Uterine Epithelial Proliferation Are Mediated Indirectly through Connective Tissue

Development of methodologies to produce mice in which a specific gene had been knocked out or disabled at the end of the 1980s provided a powerful new tool to establish the role of various proteins in reproduction in ways that had not been previously possible. This original technique and subsequent variations such as conditional knockouts that allowed a gene to be deleted in a specific cell type or at a particular time have been mainstays of reproductive biology research and have provided important insights into many aspects of reproductive biology and steroid endocrinology for over two decades, and continue to do so today. Knockouts of key enzymes that are involved in steroid hormone synthesis (e.g., aromatase), co-factors in steroid hormone signaling or downstream mediators of steroid hormone action have all provided key insights into steroid hormone actions, but knockouts of steroid hormone receptors have been the most critical in advancing our understanding of steroid hormone action.

The first of these was a knockout of ESR1 by Lubahn, Korach and Smithies (Lubahn et al., 1993). Using tissues from this *Esr1* knockout (*Esr1*KO) mouse, definitive proof was obtained that estrogen-induced uterine epithelial proliferation was mediated indirectly through ESR1 in the uterine mesenchyme/stroma (Cooke et al., 1997). In contrast, production of epithelial secretory proteins required both epithelial and stromal ESR1 (Cooke et al., 1997). Critical progesterone effects on uterine epithelium were mediated indirectly through the stroma as well, as progesterone inhibition of estrogen-induced uterine epithelial proliferation was also shown to be mediated through stromal PR.

Use of a Transgenic Mice Lacking ESR1 Expression in Uterine Epithelium

The development of conditional knockout mice where ESR1 is deleted only in the epithelium of organs such as the uterus and oviduct has recently provided an elegant model system for determining the role of loss of epithelial ESR1 in certain reproductive organs (Winuthayanon et al., 2010). In addition to confirming earlier results that estrogen-induced uterine epithelial proliferation is mediated through stromal ESR1, results from this mouse have shown that epithelial ESR1 in both the oviduct and uterus is necessary for fertility, and that uterine implantation requires epithelial ESR1 (Winuthayanon et al., 2010).

How Does Mesenchyme/Stroma Regulate Epithelial Proliferation and Other Processes in Response to Estrogen in Uterine Epithelial Cells?

The demonstration that estrogen-induced uterine epithelial proliferation is mediated indirectly through mesenchymal/stromal ESR1 raised the obvious question of how uterine mesenchymal/stromal cells stimulate proliferation in overlying epithelium.

Cell–cell communication between stromal and epithelial cells seemed unlikely, since the basement membrane on which the uterine epithelium rests should preclude direct cell–cell contact with the underlying connective tissue. This suggested that other means of communication, such as production of diffusible stromal factors that could affect neighboring epithelial cells, were most likely. It was also possible that stromal cells could have effects on the basement membrane, either by inducing compositional changes or by altering or activating growth factors present there, which could result in changes in epithelial proliferation.

Uterine Epithelial Proliferation Is Induced by Stromal Factors Produced in Response to Estrogen Stimulation, and Progesterone Inhibits the Production of these Stromal Factors

Despite work by many laboratories, it took almost 15 years from the initial demonstration that estrogen-induced uterine epithelial proliferation and progesterone inhibition of this process were mediated indirectly through uterine stromal ESR1 and PR until the stromal factors involved in these processes were identified. In 2011, Li et al. (Li et al., 2011) used a conditional knockout of HAND2, a basic helix–loop–helix transcription factor expressed in the uterine stroma, to show that this protein is induced by P4 in the uterus. Importantly, loss of HAND2 abolished P4 inhibition of estrogen-induced uterine epithelial proliferation, suggesting that HAND2 was essential for normal stromal P4 effects. HAND2 expression was shown to induce production and secretion of a group of stromal FGFs that then cross the basement membrane and act through FGF receptors on the LE to stimulate epithelial ERK1/2 signaling that normally occurs in response to estrogen treatment and drives proliferation. Thus, this landmark study determined the mechanisms both for estrogen-induced epithelial proliferation through stromal ESR1 as well as P4 inhibition of this effect through stromal PR.

Reciprocal Epithelial–Stromal Communication Is Critical for a Variety of Hormone Responses

Although uterine stromal–epithelial communication that mediates mitogenic estrogen effects on uterine epithelium and inhibitory P4 effects on this process are probably the best characterized, recent evidence suggests extensive cell–cell communication between different uterine cell types is essential for other aspects of normal uterine function. This involves reciprocal epithelial–stromal communication, as well as intraepithelial communication between LE and GE.

Leukemia inhibitory factor (LIF) in the uterus is produced primarily by GE under the influence of estrogen. It has been known for years that LIF is necessary for embryo attachment and implantation [reviewed in (Hantak et al., 2014)], but recent results examining LIF signaling have revealed complex crosstalk between various uterine cell types that are essential for normal function. In response to LIF signaling, STAT3 is activated in uterine epithelium (Fig. 1C). Use of a mouse with a conditional knockout of STAT3 only in uterine epithelium [reviewed in (Hantak et al., 2014)] revealed that STAT3 is necessary for normal LIF effects on epithelial junctional integrity that are involved in implantation. Recently, conditional deletion of LIF PR-expressing cells of the uterus was shown to cause implantation failure. Critically, loss of only epithelial STAT3 impaired stromal cell differentiation and proliferation. Additional work indicated that this effect resulted from loss of epithelial production of various members of the EGF family of ligands normally induced by epithelial STAT3 signaling that act through stromal receptors to regulate their differentiation (Fig. 1C). This unexpected signaling pathway from GE to LE to stromal cells to regulate key implantation events [Fig. 1C; reviewed in (Hantak et al., 2014)] illustrates both the complexity and importance of cell–cell signaling in uterine endometrium.

Other stromal–epithelial communication in the uterus has also been documented. A member of the hedgehog family of proteins, Indian Hedgehog (IHH) is stimulated by P4 and is a major mediator of P4 action in the uterus. Following stimulation by P4, IHH produced in the uterus induces production of the transcription factor COUP-TFII in the uterine stroma (Fig. 1B). Results from the last decade have finally established the molecular basis of critical intra-uterine signaling pathways, and undoubtedly other stromal–epithelial signaling pathways will be revealed and characterized in the decades to come.

It is likely that uterine myometrium also participates in uterine cell–cell communications, both as a source and target of signals from other uterine cell types, although this has not yet been established. Thus, all major uterine cell types may be involved in communication with other uterine cell types/compartments, and it is becoming increasingly clear that this intrauterine communication is a major factor in normal uterine function and hormonal response.

Communication between Uterine Tissues and the Uterine Microbiome

A rapidly expanding literature indicates that the gut microbiome present in humans and other animals has wide-ranging effects on metabolism, body weight and other aspects of the host animal's physiology. In recent years, a microbiome has been demonstrated in the uterus, and abnormalities in this uterine microbiome have been linked to implantation failure and pregnancy loss (Moreno and Franasiak, 2017). Based on emerging data regarding the critical role of the microbiome in the uterus, it is becoming increasingly clear that cell–cell interactions in the uterus are not confined exclusively to the constituent cells of the uterus, but extend to interactions between the uterine microbiome and the endometrium as well.

Uterus-Hormonal Regulation

Tae Hoon Kim and Jae-Wook Jeong, Michigan State University College of Human Medicine, Grand Rapids, MI, United States

Introduction

The uterus consists of heterogeneous cell types that undergo dynamic changes to support embryo development and implantation. The mature uterus consists of three tissue layers, the endometrium, myometrium, and serosa. The serosa is a single outer cell layer of tissue made of epithelial cells that envelop the uterus. The myometrium is the muscular layer, composed of inner circular and outer longitudinal smooth muscle layers. The endometrium is the most active layer and composed of stroma and epithelial cells (Brody and Cunha, 1989).

The ovarian steroid hormones estrogen (E2) and progesterone (P4) are essential regulators of uterine functions necessary for embryo implantation, development, and normal pregnancy, and the balance of these two steroid hormones working cooperatively is required for the maintenance of a healthy endometrium (Fig. 1) (Dharma et al., 2001; Wood et al., 2007). These steroids act primarily through their respective cognate nuclear receptors, the progesterone receptor (PGR) and the estrogen receptor (ESR). E2 stimulates proliferation of both the uterine epithelial and stromal cells in neonatal mice. However, this proliferative action of E2 is restricted to epithelial cells in the adult mouse uterus (Martin et al., 1973a; Huet-Hudson et al., 1989). In contrast, while P4 is inhibitory to E2-mediated proliferation of the luminal and glandular epithelial cells, P4, alone or in conjunction with E2, leads to uterine stromal cell proliferation (Huet-Hudson et al., 1989; Martin et al., 1973b; Paria et al., 1993).

The cross talk between epithelial and stroma cells changes due to P4 and E2 (Franco et al., 2012; Winuthayanon et al., 2010). These changes are critical for embryo implantation and development. E2 regulates uterine epithelial proliferation unlike P4 which inhibits the E2-induced proliferation of the epithelium (Martin et al., 1973a,b). P4 inhibits the proliferation via stromal-epithelial cross-talk. Successful embryo apposition, attachment, and implantation can be established under well-organized uterine receptivity (Wetendorf and DeMayo, 2012). A defect in maintaining the status of uterine receptivity is the major cause of most pregnancy losses. The ability of ovarian steroids to mediate endometrial proliferation occurs through the ability of hormonal stimulation to regulate growth factor communication networks between the uterine stromal and epithelial cells. P4 inhibits E2-stimulated epithelial cell proliferation in the uterus by the regulation of gene expression in endometrial stromal cells (Rubel et al., 2010).

Inappropriate activation of endometrial proliferation and differentiation by dysregulation of steroid hormones is one of the major features of uterine disease (Kao et al., 2003). Uterine diseases of the female reproductive tract represent a significant women's health problem. Excessive uterine proliferation caused by dysregulation of the steroid hormones results in several uterine diseases including infertility, endometriosis, and endometrial cancer (Bokhman, 1983; Sherman et al., 1997; Deligdisch and Holinka, 1987; Kurman et al., 1985). Endometrial cancer is a frequently occurring gynecological disorder (Siegel et al., 2016). Estrogen-dependent endometrioid carcinoma is the most common type of gynecological cancer. Endometriosis was found in 10% of reproductive-age women, and 35%–50% of infertile women had endometriosis (Jemal et al., 2006; Eskenazi and Warner, 1997; Bulun, 2009). Understanding the role of steroid hormone regulation of uterine function is critical in evaluating the pathology of these uterine diseases.

Progesterone

Progesterone (P4) is one of the major ovarian steroid hormones. P4 is produced by the corpus luteum in the ovaries (Graham and Clarke, 1997), and its synthesis and secretion are regulated by luteinizing hormone and chorionic gonadotropin during the menstrual cycle and pregnancy (Graham and Clarke, 1997). P4 is absolutely necessary for uterine implantation, decidualization, and maintenance of pregnancy (Wetendorf and DeMayo, 2012). Implantation is the most critical step to establish pregnancy in the uterus. Successful implantation requires the attachment of the embryo to a uterine luminal epithelium and its subsequent

Fig. 1 Steroid hormone regulation of endometrium.

invasion into the stromal tissue (Young, 2013). P4 prepares the endometrium to implant the embryo into the uterine epithelium and maintain the pregnancy after fertilization and implantation (Mote et al., 1999). After implantation, the uterine stroma of the surrounding implantation site starts to proliferate and differentiate, resulting in decidual cells that support the growth of the embryo which is known as decidualization (Cha et al., 2012). Importantly, the high level of P4 is maintained to control the generation of other eggs throughout the pregnancy progression, and to inhibit lactation before birth (Capuco and Akers, 2009).

P4 has an important role in the regulation of the immune and endocrine system, which mediate the role of the trophoblasts at the implantation site (Drake et al., 2001). Trophoblasts are cells that form the outer layer of a blastocyst which plays a critical role in embryo implantation and interaction with the decidual cells (Red-Horse et al., 2004). It is reported that P4 increases the cytokines released by Th2 cells which are dominant within the decidua in early pregnancy, resulting in the maintenance of pregnancy. Th2-induced cytokines trigger the secretion of hCG from trophoblasts. The secreted hCG leads to P4 production from the corpus luteum in pregnancy (Drake et al., 2001). This supports the maintenance of pregnancy by P4.

Estrogen

Estrogen (E2) is an imperative hormone that stimulates uterine epithelium capacity and regulates the menstrual cycle. Its interplay with P4 is critical in the changes of the uterus during pregnancy (Hantak et al., 2014). E2 is highly secreted by ovaries, and secretion peaks at ovulation and its level is rapidly decreased after ovulation (Burns and Korach, 2012). Before ovulation, E2 plays an important in the regeneration and growth of the endometrium. E2 prepares the endometrial tissue to respond to progesterone after ovulation (Groothuis et al., 2007).

The proliferation of the uterine endometrium is triggered by E2. This phenomenon enhances the growth of the endometrium and increases the uterine weight. E2 also helps the uterine wall to slough off dead tissue during menstruation (Gargett et al., 2012; Vasquez and DeMayo, 2013). In addition, E2 is the most important hormone in preparation for parturition. E2 stimulates proliferation in the myometrium, accomplishing the considerable growth that is necessary for the forceful contractions of labor (Kumar and Magon, 2012; Kota et al., 2013).

Steroid Hormone Receptors

Nuclear receptors are a family of ligand-activated transcription factors that are activated by steroid hormones, such as estrogen and progesterone, and thyroid hormones, oxysterols and fat-soluble vitamins. After nuclear receptors are activated, their main function is to regulate gene expression for numerous biological processes including cell proliferation, development, and reproduction as transcription factors (Tsai and O'Malley, 1994). Nuclear receptors include several distinct modular domains for transactivation regions (AF-1), DNA-binding domain (DBD) that includes two Zn fingers, ligand-binding domain (LBD) that contributes to interactions of the subset of nuclear receptors on their mode of action, and hormone response elements (HRE) act as binding regions for steroid hormone receptors (Sever and Glass, 2013).

Steroid hormone receptors, in particular the progesterone and estrogen receptors (PGR and ESR), are important functional regulators of female reproductive biology. PGR and ESR are members of the nuclear receptor superfamily. PGR and ESR1 are expressed in all compartments of the uterus, and their tight regulation is critical for uterine function (Large and DeMayo, 2012). The steroid hormones, P4 and E2, exhibit their effects via the progesterone receptor (PGR) and estrogen receptors (ESR). PGR and ESR regulate the effect of P4 and E2 under physiological conditions, either by activation of P4 or E2 target genes transcription on the uterine tissues (Li and O'Malley, 2003; Acconcia and Kumar, 2006).

The ovarian steroid P4 mediates its effects through the PGR, which belongs to the nuclear receptor superfamily. As in all members of this family, the PGR contains modular functional domains. The PGR contains an N-terminal transactivating function domain (AF-1), a central DNA binding domain, and a ligand binding domain with a second activation domain (AF-2) (Sever and Glass, 2013). The PGR is found as two major isoforms, PRA and PRB, which are expressed from one gene with two alternative translation start sites. The PRB isoform contains an additional 164 amino acids at the N-terminus and a third activation domain (AF-3) (Wierman, 2007).

The importance of PGR in uterine function was demonstrated with the genetic ablation of PGR in mice (PRKO), which results in pleiotropic reproductive defects including those of sexual behavior, gonadotropin regulation, anovulation, lack of decidualization, and mammary branching morphogenesis. Ablation of PGR does not impact uterine development or morphology. However, ablation of PR renders the mouse uterus incapable of supporting embryo implantation (Lydon et al., 1996).

The total level of PGR and the ratio of PR-A/PR-B varies in reproductive tissues. The function of PR-A and PR-B were studied using an animal mouse model. Ablation of PRA alone (PRAKO) demonstrated that PRA is the major mediator of P4 signaling in the mouse reproductive tract, and these mice show similar ovarian and uterine abnormalities seen in the PRAKO mice. In addition, the PRAKO mice, in which PRB is solely expressed, show an abnormal P4-induced proliferative effect on the epithelium in opposition from its normal antiproliferative inhibition of E2. Ablation of the PRB isoform (PRBKO), although exhibiting mammary morphogenesis defects, did not display any uterine phenotype, and the mice were fertile (Vasquez and DeMayo, 2013). The mice with ablation of specific PR-A and PR-B demonstrated that PR-A plays a crucial role in the mouse uterus and PR-B is mediated in mammary gland maturation (Kariagina et al., 2008).

ESR1 and ESR2 are expressed in distinct tissues. ESR1 is mainly expressed in the mammary glands, pituitary, hypothalamus, ovarian theca cells and uterus, while ESR2 is detected in the ovarian granulosa cells, lung and prostate. ESR1 expression is regulated by very firm hormonal and temporal control, indicating spatial and temporal roles during implantation. Specific ablation of epithelial ESR1 in the murine uterus led to infertility due to dysregulated estrogen signaling. It was discovered that epithelial ESR1 has an important role in the regulation of epithelial apoptosis, while stromal ESR1 mediated E2-induced epithelial proliferation (Vasquez and DeMayo, 2013; Wierman, 2007; Deroo and Korach, 2006).

Interactions with many transcriptional coregulators are required to activate PGR and ESR1 signaling. These coactivators or corepressors make large complexes that engage in the remodeling of chromatin through histone post-translational modifications, and link transcription factors to the basal transcriptional RNA polymerase II machinery for all subsequent genomic actions (Szwarc et al., 2015). Steroid receptor coactivator (SRC) family members (SRC-1, SRC-2, SRC-3) interact with nuclear receptors and enhance target gene transcription. The function of steroid receptor coactivator is associated with regulation of steroid hormone signaling. Many studies have found that steroid receptor coactivator plays an important role in the regulation of reproductive biology including ovulation, implantation, and parturition. Furthermore, dysregulation of steroid receptor coactivator actions led to infertility, cancer, and endometriosis (Szwarc et al., 2014; Losel and Wehling, 2003).

Nongenomic Actions of Steroid Hormones

According to the classical model (genomic action) of steroid action, in the absence of P4 and E2 hormones, PGR and ESR1 are localized in the cytoplasm. To make an activated state of PGR and ESR, after hormone binding, it undergoes a conformational change and translocates to the nucleus where it regulates target gene expression. In contrast, a nongenomic action is distinguished from genomic steroid actions (Fig. 2). These responses are known as “non-classic,” “non-genomic” or “extra-nuclear” steroid effects.

Fig. 2 Steroid hormone actions. Modified from Boonyaratankornkit, V. and Edwards, D. P. (2007). Receptor mechanisms mediating non-genomic actions of sex steroids. *Seminars in Reproductive Medicine* 25(3), 139–153.

Nongenomic actions are (1) observed in some cell types without a nucleus such as erythrocytes and platelets; (2) not blocked by inhibitors of transcription; (3) very rapid actions; (4) initiated by membrane-steroid signaling (Losel and Wehling, 2003).

In the uterus, this transcriptional activation can also occur in a ligand independent fashion as a result of phosphorylation of PGR and ESR1. In addition, PGR and ESR1 interact with src to activate the MAP kinase pathway to regulate target genes during the regulation of nuclear receptors target genes, and coregulator complexes are formed (Vasquez and DeMayo, 2013; Tsai and O'Malley, 1994; Li and O'Malley, 2003; Szwarc et al., 2014). Nongenomic E2 plays a crucial role in the regulation of endometrial inflammatory response during implantation, pregnancy, and menstruation by modulating gene expression and secretion that support fertilization and embryo viability. Furthermore, nongenomic E2 exhibits effects on the calcium-signaling pathway that are associated with muscle contraction in the reproductive tract (Solar and Velasquez, 2013).

Three membrane progesterone receptors are identified: mPR α , mPR β , and mPR γ in a variety of species. mPRs modulate the activity of various signal transduction cascades binding P4, including modulation of ERK1/2 or p38 MAPKs, inhibition of cAMP production. Furthermore, these membrane proteins are also associated with eliciting contraction in parturition (Losel and Wehling, 2003).

Dysregulation of Steroid Hormone Signaling

E2 induces proliferation of epithelial cells in the uterus, while P4 has an inhibitory effect on E2-induced proliferation (Martin et al., 1973a,b). An unbalancing of this steroid signaling causes infertility and several gynecological diseases such as endometriosis, endometrial cancer, and leiomyomas. The major pathologic phenomenon of uterine disease is the dysregulation of ovarian steroid hormones across epithelial proliferation and apoptosis in the uterus (Bokhman, 1983; Sherman et al., 1997; Deligdisch and Holinka, 1987; Kurman et al., 1985). These uterine diseases display characteristic dysregulation of PGR and ESR expression and of their downstream target genes in their pathologies. All of these disorders have been mainly associated with increased E2 sensitivity or dysregulation of P4. Loss of functioning P4 signaling leads to P4 resistance, either at the level of the PGR or its target genes, and it can lead to the disruption of the critical epithelial-stromal cross talk. The antagonistic effect of P4 on E2 forms the rationale for progestin-based therapeutics for endometrial cancers (Benshushan, 2004; Minaguchi et al., 2007; Hahn et al., 2009; Yamazawa et al., 2007). However, many studies indicate limiting the use of P4 therapy due to its low response rates (Ramirez et al., 2004; Park et al., 2012; Decruze and Green, 2007; Randall and Kurman, 1997; Kim et al., 1997). Resistance to P4 treatment, via loss of progesterone receptors (PGR) or its signaling pathways, is a major hurdle in the treatment of many of diseases in the endometrium of women including endometriosis and endometrial cancer (Al-Sabbagh et al., 2012; Burney et al., 2007; Soyal et al., 2005; Attia et al., 2000).

The endometrium undergoes well-defined and regulated gene expression in preparation for implantation. The timing of endometrial receptivity coincides with the down-regulation of epithelial ESR1 in normal mid-secretory endometrium. P4 and PGR are essential for successful embryo implantation, but there is a shift in PGR out of the epithelium to the stromal compartment that also occurs during the implantation. Persistence of ESR1 and PGR in the glandular epithelium is associated with infertility and suspected implantation defects. Infertility is a major reproductive health problem. Assisted reproductive technologies (ART) is the gold standard tool to help couples who had pregnancy failure due to an implantation defect (Levgur et al., 2000). P4 supplementation has been studied to improve the success of ART (Allahbadia, 2015; Practice Committee of American Society for Reproductive Medicine, 2008). P4 supplementation is associated with improvement of implantation and pregnancy rates, compared to treatment with placebo or no treatment. In addition, any type of P4 supplementation administration enhanced pregnancy outcomes in ART cycles (van der Linden et al., 2015).

The efficacy of P4 supplementation in women with unexplained recurrent miscarriages were investigated, considering its role in pregnancy (Hussain et al., 2012; El-Zibdeh and Yousef, 2009). Several clinical trials were studied to improve the pregnancy outcome that is associated with P4 supplementation in unexplained infertility or recurrent pregnancy loss patients (El-Zibdeh and Yousef, 2009; Clifford et al., 1997). A study on 203 women who had experienced at least three unexplained recurrent miscarriages was randomized to receive P4 supplementation for examining the miscarriage rate. The incidence of miscarriage rate was lower in the P4 treated group than in the untreated group when compared with historical data. The majority of cited clinical trials revealed that P4 supplementation can have beneficial effects in women with otherwise unexplained recurrent miscarriages (Hussain et al., 2012). P4 supplementation can be administrated via vaginal suppositories, intramuscular injection or oral intake (Walch and Huber, 2008).

Endometrial cancer is the most often diagnosed disease of the female uterus in the United States and the incidence of new cases has increased over the past several decades (Siegel et al., 2016). The major treatment for endometrial cancer is surgery to remove the uterus and cervix (called a hysterectomy) (ACOG Committee, 2009; Temkin et al., 2016). Although most cases of endometrial cancer are diagnosed in post-menopausal women, 5% of women have endometrial cancer before age 40 and 20%–25% are diagnosed with endometrial cancer before menopause (Pellerin and Finan, 2005). Furthermore, the number of endometrial cancer diagnoses in younger patients will continue to increase due to an increase of known endometrial cancer risk factors such as obesity, high blood pressure, and diabetes mellitus (Chassot et al., 2002; Charytan et al., 2012; Varon and Marik, 2008).

A steroid hormone imbalance could lead to aberrant endometrial proliferation and endometrial cancer. P4 therapy has been used in the conservative endocrine treatment of endometrial complex atypical hyperplasia and early endometrial cancer in young women with a desire to maintain their fertility (Hahn et al., 2009; Kim et al., 2013). P4 and its analogues can have an effect on

suppression of endometrial cancer proliferation (Yang et al., 2011). However, more than 30% of patients fail to respond to progestin due to de novo or acquired P4 resistance (Decruze and Green, 2007). Further, P4 resistance is seen in a wide variety of endometrial diseases such as infertility, endometriosis, as well as endometrial cancer. Therefore, the identification of P4-regulated signaling pathways in the uterus is crucial for understanding the impairments that underlie disruption of steroid hormone control of uterine cell proliferation and differentiation.

Endometriosis is defined as the presence of endometrial cells outside of the uterine cavity. Endometriosis is one of the most common causes of chronic pelvic pain, dysmenorrhea, and infertility, affecting 10% of all reproductive age women and 35%–50% of infertile women (Eskenazi and Warner, 1997; Bulun, 2009; Kim et al., 2013; Johnson and Hummelshoj, 2013; Burney and Giudice, 2012). Surgical excision of lesions and hormonal suppression are the current gold standards of therapy, but both approaches are associated with a significant risk of morbidity and a high incidence of relapse (Bulun, 2009; Sinaii et al., 2002). Therefore, identification of mechanisms involved in the pathogenesis of endometriosis and development of novel therapies are critical. Endometriosis is an estrogen (E2) dependent, inflammatory condition. Pro-inflammatory cytokines contribute to chronic pelvic pain and inflammation, the latter a key factor for pathogenesis and pathophysiology (Bulun, 2009).

Adenomyosis is a common benign gynecological disease caused by the presence of endometrial glands and stroma found within the myometrium (Tamai et al., 2005; Ferenczy, 1998). The prevalence of adenomyosis ranges from 10% to 66% in women diagnosed at the time of hysterectomy (Vercellini et al., 2006). Adenomyosis is one of the most common causes of menorrhagia, dyspareunia, dyschezia, dysmenorrhea, and chronic pelvic pain (Levgur et al., 2000). Most women are not diagnosed until later stages of the disease and invasive surgical intervention is required for severely symptomatic women due to less of an effect of pharmacological therapy (Vercellini et al., 2006).

The Primate Uterus: Cyclic Changes

By Daniel Slayden and Andrea Calhoun, Oregon National Primate Research Center, Beaverton, OR, United States

© 2018 Elsevier Inc. All rights reserved.

Glossary

Basalis zone The deepest zone of the endometrium adjacent to the myometrium.

Decidualization The postovulatory transformation of the stromal compartment of the endometrium in preparation for pregnancy.

Endometrium The inner mucosal lining of the uterus.

Functional Zone The upper zones of the endometrium that undergo cycling differentiation and shedding.

Menstruation Cyclic shedding of the upper zones of the endometrium at the beginning of each menstrual cycle.

Myometrium The smooth muscle layer of the uterine wall.

Spiral Arteries Coiled arteries that supply blood to endometrial functionalis zone during the luteal phase of the menstrual cycle.

Old World monkeys (Cercopithecidae) have reproductive tract anatomy and menstrual cycles similar to women. Herein, we describe the cyclic effects of steroid hormones on the primate uterus. In previous reviews we reference the historic literature extensively (see References). The focus here will be on nonhuman primates (NHPs) including rhesus (*Macaca mulatta*) and cynomolgus macaques (*M. fascicularis*), which our laboratory has studied extensively, with brief comparisons to other species including the vervet (*Chlorocebus aethiops*), the baboon (*Papio*), and women. At the beginning of each cycle, the luminal portion of the uterine lining, the endometrium, of these species is sloughed in menstruation. Macaques, baboons, and women display “frank” menstruation where bleeding is detectable externally. In contrast, the vervet displays minimal bleeding that can only be detected by vaginal swab. After menstruation, estradiol (E_2) secreted by the ovary during the follicular phase of the cycle stimulates endometrial cell proliferation and regrowth. Thus, the follicular phase is also referred to as the proliferative phase. In primates, the typical proliferative phase is 10–14 days but can be highly variable in length. After ovulation, progesterone (P_4) secreted from the corpus luteum stimulates endometrial secretory differentiation in preparation for embryo implantation. If embryo implantation does not occur, the luteal (secretory) phase of the cycle usually lasts for 12–14 days. The decline of P_4 at the end of the cycle (approximately 28 days) triggers menstruation. Estrogen and P_4 are the only ovarian factors needed to elicit cyclic responses in the uterus. In a proof of concept study, Hodgen (1983) demonstrated that pregnancy could occur in an ovariectomized macaque treated with E_2 and P_4 in this sequential fashion. In that study, an embryo was transferred into the fimbrial ostium, indicating that both fallopian tube and uterine function were preserved by E_2 and P in the absence of ovaries.

Cyclic Changes in Morphology

The primate (simplex) uterus can be divided into the fundus (dome-shaped top), the corpus (body), and the isthmus (neck) which leads into the cervix. Fig. 1 shows a picture of a macaque uterus. The endometrium that lines the uterine cavity is surrounded by a muscular wall, the myometrium. Fig. 2 shows full-thickness histological sections of the macaque endometrium. During menstruation (Fig. 2A) the upper portion of the endometrium is friable with evidence of breakdown and bleeding (Fig. 2D) of the luminal surface. In the proliferative and secretory phases of the cycle, the luminal surface displays a simple columnar epithelium, which is ciliated in women but predominately nonciliated in macaques and baboons. The primate endometrium contains simple tubular or branched glands that extend to the endometrial–myometrial border. The lamina propria or stroma is a highly cellular connective tissue with an amorphous extracellular matrix. The macaque and human endometrium were described by Bartelmez (1933, 1951) as having four morphological zones. Zone I is defined as the surface epithelium with an underlying band of stromal cells. Zone II the glands that run perpendicular to the surface, and deeper; Zone III contains branched glands. Zone IV is the basal layer where the glands terminate adjacent to the myometrium. Zones I–III are commonly termed the functionalis zones because these zones undergo cyclic secretory differentiation and menstrual sloughing. Zone IV, the basalis zone, is reported to be relatively unresponsive to hormonal changes in women, but in the macaque, the basalis zone undergoes cell proliferation in the early secretory phase of the cycle. Development of zonal anatomy is dependent on ovarian steroids and in premenarchial and postmenopausal primates the zonal anatomy is often indistinct. Hormone supplementation or replacement in postmenopausal animals results in reappearance and hypertrophy of the zones.

The myometrium surrounds the endometrium with four distinct layers of smooth muscle that include (1) the *stratum submucosum*, longitudinal muscle fibers underlying the endometrium; (2) the *stratum vasculare*, a blood vessel-rich layer with fibers running in multiple directions; (3) the *stratum supravascular*, a layer of circular and longitudinal bundles; and (4) the *stratum*

Fig. 1 Macrophotograph showing half of a proliferative phase rhesus macaque uterus that has been cut along the longitudinal axis. A solid black line has been drawn to delineate the endometrial–myometrial border, and a dashed line has been drawn to delineate the plane of sectioning for histological analysis.

Fig. 2 Photomicrographs of glycol methacrylate embedded, Hematoxylin/Eosin stained sections of rhesus macaque endometrium showing cyclic changes in histology. Phase of the menstrual cycle is shown in columns. A black line has been drawn on the full thickness sections to show the myometrial border. *Endo*, endometrium; *Myo*, myometrium; *Mi*, mitosis; *G*, gland; *S*, stroma; *Ar*, spiral artery.

subserosum; a layer that is continuous with the myosalpinx (oviduct) and the connective tissues of the broad ligament. Blood vessels, individual nerve fiber, and nerve bundles intersect these layers. A unique junctional zone adjacent to the endometrial basalis has been extensively studied in women by magnetic resonance imaging and macaques by ultrasound.

The pattern of vascular circulation in the primate uterus has been described in a series of classic papers (Bartelmez, 1956, 1957). Briefly, the uterine artery on each side enters the uterus and runs as an arcuate artery to supply the myometrium. The arcuate sends numerous radial arteries into the endometrium. The functionalis zone derives its blood supply from specialized spiral arteries (Fig. 2C and F). Basal arteries supply the basalis zone. In an alternative classification the arteries that vascularize the functionalis zone are called Type I endometrial arteries, and the basal arteries that only vascularize the basalis and lower part of Zone III as Type II. The basal arteries produce a capillary bed that maintains the viability of the lower regions when the upper layers slough and degenerate during menstrual breakdown.

Noyes et al. (1950) created a scheme for morphologically dating the endometrium of women relative to an ideal 28-day cycle, and similar cyclic changes have been described in NHPs. In this scheme, the first day of menstruation is designated cycle day 1, and menses typically lasts 2–5 days. After menstruation in the early proliferative phase the endometrial glands are straight and short, and the stroma is compacted. By the midproliferative period (days 8–10), the glands are longer with abundant mitotic cells (see Fig. 2E), and a mitotically active stroma is somewhat edematous. In the late proliferative phase (days 11–14), the rapidly growing glands become more tortuous, and the epithelium appears pseudostratified due to the accelerated proliferation of the elongated cells. The stroma continues to be mitotically active and is less edematous than during the midproliferative stage. The effects of the P_4 are evident by the second day after ovulation (day 16 in an ideal cycle). At this time, glycogen accumulates in the basal portion of the glandular epithelium, displacing the nuclei and creating a pseudostratified appearance. Glycogen is often solubilized in histological preparations, leaving the appearance of vacuoles in the cells. By mid-secretory phase (days 18–20) the vacuoles become smaller as glycogen moves into the apex of the cells (see Fig. 2F), continuing into the gland lumen. On cycle days 21 and 22 the endometrial stroma becomes highly edematous. On day 23 stromal cells surrounding the spiral arterioles begin to enlarge and along with stromal mitoses constitutes the earliest visible predecidual change. By day 24, in the macaque, predecidual cells are observed cuffing the spiral arterioles and stromal mitoses are more numerous. By day 25, hypertrophied stromal cells are present under the surface epithelium, and by day 27, the upper portion of the endometrial stroma consists of a sheet of well-developed decidual-like cells. Lymphocytes and polymorphonuclear leukocytes invade the upper regions on days 25–27. The glands dilate during the late secretory phase giving glandular epithelium a saw-toothed appearance, with shrunken nuclei and jagged apical surfaces, an appearance that has been referred to as secretory exhaustion.

The Noyes criteria for endometrial dating have been challenged, primarily for its use in diagnosing the impact of low P_4 in the secretory phase (luteal-phase deficiency) and for determining the fertile window for embryo transfer. Advances in the genomics of endometrial receptivity have identified an array of molecular biomarkers that can better define the window of embryo implantation. More recently, the endometrial proteome has been probed by MALDI-MS to unveil an array of differentially expressed proteins that define the receptive endometrium of women.

Cell Proliferation

To circumvent the pitfalls of Noyes criteria and precisely time endocrine control of the monkey reproductive tract, we have sequentially treated macaques with implants that release E_2 alone for 14 days (an artificial proliferative phase) and then E_2 plus P_4 for 14 days (an artificial secretory phase). In this model E_2 priming results in tubular glands with abundant mitotic cells identical to the follicular phase of the natural cycle. In our studies and those of others, immunohistochemistry (IHC) for proliferation-associated markers including Ki-6, phosphor H3 (a marker of mitotic cells), and in vivo labeling with bromodeoxyuridine has been used extensively to detect and quantify cell proliferation. All three techniques show similar trends during the cycle. Fig. 3 shows IHC staining for Ki-67 in the macaque endometrial functional and basalis zones.

Use of artificial cycles has demonstrated that cell proliferation is minimal in both the functionalis and basalis zones during menstruation. The endometrium that remains after menstruation has a ragged and torn surface marked by multiple gland openings surrounded by denuded stroma that lacks a covering epithelium in both macaques and women. Healing of this denuded stromal surface begins with the transformation of the uppermost gland cells into a migratory phenotype. These cells proliferate and move out from the necks of the glands, spread out, and meet migrating cells from other glands to form a new luminal surface (Ludwig and Spornitz, 1991). In the macaque there are abundant proliferating cells in the Zone 1 glands, but epithelial cell proliferation in the basalis is quiescent (compare Fig. 3B and E). Healing is complete by 4–5 days after P_4 withdrawal at which time estrogen-dependent mitotic activity begins in the uppermost regions of the glands. Counts of proliferating cells reveal that almost all of the epithelial cell replacement during the late proliferative phase occurs in the mid- and upper-functional zones. Also during the proliferative phase, the upper zones contain abundant apoptotic cells, indicating a balance of cell death and cell birth, with the overall trend toward more growth. Apoptosis and phagocytosis of dead cells play major roles in endometrial remodeling. The spiral arteries are extensively remodeled or partially lost during menstruation. New growth in the proliferative phase features small vessels in the upper functionalis zone, appearing to peak on Day 8.

In the artificial cycle the effects of P_4 on the epithelium (Fig. 3G–I) become evident on cycle day 17, after day 3 of P_4 treatment. P_4 gradually suppresses cell proliferation in the glandular epithelium of the functionalis zone and induces hypertrophy and

Fig. 3 Immunostaining for Ki-67 a marker of cell proliferation in the proliferative and secretory phases of the cycle. Slides were stained with the antihuman Ki-67 antibody (Dako Corp.; Carpinteria, CA); positive staining is dark brown.

accumulation of glycogen in epithelial cells. Conversely, the basalis zone, which is quiescent during the proliferative phase, displays an intense period of cell proliferation that gradually subsides by late secretory phase.

Menstruation

Old world monkeys, like women, exhibit true menstruation in which the functionalis zone of the endometrium is shed each cycle. In the macaque, exposure to P_4 (< 1 ng/ml in serum) for at least 3 days is required to prime the endometrium for menstruation. After that, withdrawal of P_4 triggers expression of matrix metalloproteinase (MMPs) enzymes in the upper endometrial zones that are the primary effectors resulting in dissociation of functionalis zone tissues. Macaque endometrial MMP-1, -2, -3, -10, -11, and -14 transcripts peak 2–4 days after P_4 withdrawal and then declines spontaneously during the proliferative phase of the cycle. Studies in the macaque have led to the view that a “critical period” consisting of 24–30 h of P_4 withdrawal exists during which P_4 replacement will prevent tissue breakdown. After this critical period, sloughing and bleeding become inevitable even if P_4 is replaced, indicating that P_4 does not simply block MMP synthesis.

Withdrawal of P_4 results in vasoconstriction of the spiral arteries. [Markee \(1940\)](#) proposed vasoconstriction of these arteries could lead to localized ischemic hypoxia in the superficial zones. While vasoconstriction may not play a regulatory role in menses, hypoxia is a strong regulator of vascular endothelial growth factor (VEGF), and both stromal and glandular VEGF are upregulated premenstrually in the macaque endometrium. In the macaque, hypoxia-inducible factor 1 alpha (HIF-1 α) is elevated in the small vessels of the endometrial functionalis, supporting a role for hypoxia during menses.

The focal nature of menstrual breakdown and MMP expression in the mid- and upper-functional zones supports the concept that local factors such as cytokines act to relay the effects of P_4 withdrawal preceding menstruation. Studies have promulgated the concept that the entire functionalis zone is lost during menstruation and that a new functionalis arises from proliferating stem cells located in the basalis. It has been demonstrated that an entire endometrium could regenerate from remnants left after dissecting out the endometrium with a scalpel and then wiping the uterine cavity clean with a cotton swab. Adult stem cells are present in other tissues that undergo regeneration; it has been proposed that endometrial stem cells could reside within the basalis zone and account for endometrial regrowth. However, during normal menstruation, the entire endometrium is not shed, and as menstruation ends, the surface epithelium undergoes a brief period of hormone-independent healing and reepithelialization from the remaining

glands. Bartelmez and Markee proposed that during natural menstruation little tissue is shed and the reduction in the thickness of the endometrium is primarily due to loss of fluid, resulting in shrinkage of the spongy layer. As indicated above found that mitotic activity is very low in the basal region until midcycle when it increased after the periovulatory period. In the early repair phase, synthesized DNA is primarily in the gland and surface epithelial cells, involved both cellular migration and replication, and is essentially a wound-healing reaction that was not dependent upon E_2 . Moreover, the highest rates of proliferation were evident on days 8–10 in the upper third of the functionalis, not the basalis. The sum of these studies indicate that P_4 stimulates cell proliferation in the basalis while it inhibits glandular proliferation in the upper zones.

Steroid Receptors

Two estrogen receptors ESR1 and ESR2 are expressed in the endometrium and undergo cyclic changes in expression and localization. ESR1 transcript and protein increase following E_2 treatment and decrease in response to P_4 treatment in the endometrium of women and NHPs. Fig. 4A–D shows immunostaining for ESR1 in the macaque endometrium. After E_2 treatment alone for 14 days, staining for ESR1 is strongly positive in the nucleus of glandular epithelium, and in the stroma of both functionalis and basalis zones. Cotreatment with P_4 during artificial secretory phase results in a P_4 -induced blockade of E_2 -stimulated ESR1, resulting in minimal ESR1 staining in glands and stroma of the functionalis zone. However, P_4 does not inhibit ESR1 expression in the glands and stroma of the basalis zone. Unlike ESR1, ESR2 staining in the glands and stroma of the macaque does not undergo cyclic changes. Also, though there is no detectable ESR1 staining in the endothelium of endometrial vessels of the macaque or women, there is strong staining for ESR2 throughout the proliferative and secretory phases. ESR1 is detectable by IHC and in situ hybridization muscle and pericytes of the spiral arteries of macaques, baboon, and women. In the macaque and vervet, the basal arteries are negative for ESR1. Also, many of the radial and arcuate arteries in the myometrium were negative for both ESR1 protein and ESR1 mRNA. Therefore E_2 could act on the vessels through endothelial ESR2 during the whole cycle, uninfluenced by P_4 .

Two functional progesterone receptors (PGRs) (PGR-A and PGR-B) have been identified. PGR-B is a larger molecule than PGR-A due to the presence of an additional 165 amino acids in the N-terminal domain; this distinction between the two isoforms appear to cause differential expression in the human endometrium. IHC with antibodies that recognize both PGR forms (Fig. 4E–H) shows that E_2 treatment increases PGR nuclear staining in all cell types except vascular smooth muscle and endothelium. Strong staining is

Fig. 4 Immunohistochemical staining for ESR1 and PGR in endometrial cryosections, ESR1 was detected with monoclonal antibody 1D-5 (Biogenex, San Ramon, CA). PGR staining was detected with monoclonal PR Ab-8 antibody (Neomarker Inc., Fremont, CA). Strong staining was detected for both ESR1 and PGR in the glands and stroma of the proliferative phase. In the secretory phase, P_4 resulted in reduction of glandular and stromal ESR1, whereas PGR staining was retained in the stroma of the functionalis but retained in the basalis zone.

observed in both the glands and stroma during the proliferative phase. In the luteal phase or after cotreatment with P_4 , functionalis glandular PGR staining is strikingly decreased, yet PGR is retained in the functionalis stroma, basalis glands, and stroma.

PGR staining is strong in perivascular stromal cells, but there is no specific PGR staining in either the endothelium or the smooth muscle cells of the endometrial vasculature. PGR of the vascular wall is present in the spiral arteries of the functionalis but not the basalis. Consequently, we suggest that the genomic actions of progestins on some uterine vascular elements are likely to be indirect.

Androgen receptor (AR) is also present in the macaque and human endometrium. E_2 increases and P_4 decreases expression of AR mRNA and protein within the endometrial stroma. No AR is detectable in the endothelium or vascular smooth muscle of the spiral arteries.

Paracrine Factors

It is well recognized that ovarian steroids drive the synthesis of paracrine factors, which have the potential to regulate cell proliferation in target tissues. While steroid stimulation of growth factors have been reported, none have been *unequivocally* identified as a universal mediator of steroid action in the primate uterus. Among the likely contenders are the insulin-like growth factor (IGF) and epidermal growth factor (EGF) and fibroblast growth factor (FGF) families. Estrogens upregulate EGF in nonprimates and EGF has been shown to have estrogen-like effects on uterine growth. EGF mRNA is present in human endometrium and the EGF peptide has been detected by IHC. Insulin-like growth factor I and II (IGF-I, IGF-II) can that stimulate mitosis in a wide variety of tissues. Regulation of IGFs in the uterus has been studied extensively in nonprimates in which the predominant stimulator of IGF-I secretion is E_2 . Cell membrane receptors for IGF-I and IGF-II have been identified in the rodent and human endometrium in both the proliferative and secretory phases. Receptors for IGF-I appear to be increased by E_2 . IGFs are typically found bound to specific insulin-like growth factor-binding proteins (IGFBPs) that modulate their action. IGFBP-1, -2, and -3 have been reported in the human and baboon endometrium. In women, IGFBP-1 has been localized by IHC in decidualized stromal cells during both the cyclic luteal phase and pregnancy. IGFBP-1 mRNA is reported to be expressed by the secretory but not proliferative human endometrium. IGFBP can be detected via IHC in the endometrium of baboons during the late cyclic luteal phase, pregnancy, and after E_2 plus P_4 treatment, but not during follicular phase or after E_2 treatment alone. However, the histological distribution of IGFBP-1 in baboon appears to be different from that reported in women. In the nonpregnant baboon, IGFBP-1 synthesis is confined to the epithelial cells of the deep basal glands during the late luteal phase and shifts to the decidualized stromal cells during pregnancy. This pattern of IGFBP localization closely parallels IHC staining of PGR during the luteal phase and pregnancy as reviewed above, which supports the hypothesis that P_4 induces both IGFBP-1 secretion and decidualization in humans and NHPs. Two other IGFBPs, IGFBP-2 and IGFBP-3, have been examined in the human and baboon endometrium. In women, IGFBP-2 and IGFBP-3 transcripts are present in the proliferative and secretory endometrium.

Keratinocyte growth factor (KGF; FGF-7) is strikingly increased in the macaque endometrium during the secretory phase. Recent studies have indicated that KGF can also be produced by endometrial epithelial cells in several species. KGF receptor expression is primarily localized to epithelial cells, and it was proposed that KGF could play a role in regulation of epithelial cell function during the secretory phase. Administering KGF directly to the uterus via an oviductal catheter system induced antiapoptotic effects on the glandular epithelium.

Decidualization

In women, decidualization begins during the latter half of the secretory phase around the spiral arterioles and then spreads throughout the upper 2/3 of the endometrium. In the macaque, the endometrium does not fully decidualize until either pregnancy occurs or when P_4 treatment is maintained for longer than 14 days. Compared to animals treated with E_2 plus P_4 for only 2 weeks, treatment for 5 months with E_2 plus P induces a highly decidualized endometrium with enlarged stromal cells, excessive amounts of extracellular matrix in the functionalis, enlarged spiral arteries, and a greatly reduced number of glands.

In macaques the presence of an implanting conceptus stimulates the formation of an epithelial plaque on the endometrial surface (Enders, 1991). The plaque arises from a proliferation of cells of the luminal surface epithelial cells and ESR1 and PGR are negative. A striking difference observed in human and macaque endometrium is the degree to which the periarteriole stromal cells differentiate during the final week of the menstrual cycle. In the macaque, these changes that occur beyond the arterioles in the stroma are minimal in the nonpregnant animals. In this case, the stromal cells enlarge, but only cells surrounding the spiral arterioles develop decidual characteristics. Extended treatment with P_4 results in a more dramatic hypertrophy of most of the stromal cells in macaque endometrium and has been called a decidual reaction. Expression of tissue inhibitor of metalloproteinase 3 (TIMP-3) is a clear marker of decidual changes and appears first around the spiral arteries. A mechanical stimulus can be used to induce decidualization in nonpregnant rhesus monkeys in the secretory phase. Approximately 1/3 of macaques treated with chronic P_4 will develop breakthrough bleeding in the presence of decidualization. Decidualization of the endometrial stroma and glandular atrophy has also been reported in macaques treated for 14 weeks with intrauterine devices that released the synthetic progestin levonorgestrel. It is noteworthy that the effects of P_4 do not appear to require continuous E_2 support during the secretory phase; animals treated with E_2 for 14 days followed by P_4 alone undergo morphological changes that appear nearly identical to animals cotreated.

In conclusion, our studies have revealed cyclic morphological and biochemical changes in the NHP endometrium during the menstrual cycle. We conclude that these changes are identical in naturally cycling and artificially cycled macaques. These

Fig. 5 Diagram depicting the cyclic changes in endometrial thickness, vascular growth, cell proliferation, and menstruation during the menstrual cycle.

endometrial changes are summarized in Fig. 4. At the end of the menstrual cycle, immediately preceding menstruation, the action of P_4 has suppressed ESR1 and PGR in endometrial functionalis glands, yet persist in the functionalis stroma and the basalis glands and stroma. When the functional corpus luteum regresses and circulating P_4 declines, the endometrium responds within a few days by menstruating. Menstruation must therefore be considered a stromal function, as the only cells in the functionalis with PGR that could “sense” P_4 withdrawal are in the stroma. As the next cycle begins after menstruation, the endometrial surface repairs itself independent of estrogen action. Then in the proliferative phase E_2 -dependent glandular and vascular growth begins. At mid-cycle, serum P_4 rises again and the endometrium steadily responds by stromal cell enlargement, increased glandular sacculization, spiral artery development, stromal edema, and increased mitotic activity in the basalis. P_4 acts to induce the expression of an array of steroid-regulated genes in both stromal and epithelial cells, but epithelial cells lack PGR during much of this time. The ability of P_4 to keep the epithelium suppressed may be a function of PGR-positive cells located within the stroma. This also generates other mediators that affect epithelial cell response during the late luteal phase until serum P_4 declines and the cycle begins anew (Fig. 5).

Glossary

Decidualization Differentiation of the fibroblastic endometrial stromal cells into a more epithelial-like phenotype (epithelioid), known as (pre-) decidual cells. In humans, this occurs spontaneously under the influence of ovarian steroid hormones and local factors within the endometrial tissue. This differentiation process takes place progressively throughout the secretory phase of the menstrual cycle with cellular transformation becoming histologically evident during the mid-late secretory phase. In a conception cycle, these cells become the decidual component of the placenta.

Description of Menstruation

Menstruation is the process whereby most of the superficial or functionalis layer of the endometrium that lines the uterine cavity, disintegrates and is expelled from the uterine lumen at the end of the secretory phase of a nonconception cycle. In the absence of the luteotrophic signal from a developing embryo (human chorionic gonadotropin) the corpus luteum degrades leading to rapid fall in progesterone levels. This drop in progesterone is the major signal which triggers activation of the menstrual cascade of events. The first day that menstrual blood is visible defines day 1 of the menstrual cycle, with menstrual bleeding generally proceeding for 4–5 days. Our understanding of the specific mechanisms underlying menstruation is limited by the small number of species which experience menstruation as a normal physiological process; menstruation occurs in only a very few mammals—women, old-world primates, some bats, the elephant shrew and the spiny mouse. It is thought that menstruation is limited to these species as only they experience decidualization of the stroma in the absence of an embryo. Since decidualization is an irreversible differentiative process, the terminally differentiated tissue must be shed and subsequently restored for potential embryo implantation in the following cycle (Finn, 1986).

The concept of monthly menstruation is a modern world phenomenon arising from the widespread use of contraception, meaning less pregnancies and less breast feeding (lactational amenorrhoea). Thus modern women have between 350 and 400 episodes of menstruation. With a mean menstrual blood loss of 43 mL per cycle, the average woman loses more than 20 L of blood vaginally during her reproductive life. International standards now define that the 90th percentile of blood loss during each normal menstruation is >80 mL, and that anemia is significantly increased in women with a loss of >60 mL (Hallberg et al., 1966). Women with >80 mL blood loss are considered to have heavy or prolonged menstrual bleeding also known as menorrhagia. It is difficult to quantify menstrual blood loss based on the patient's history or even the use of pictorial blood loss assessment charts—actual measurement by analysis of tampons, pads or volumes harvested in menstrual cups provides the only truly accurate data. The duration of bleeding can be determined accurately with the use of menstrual diaries, adapted by the World Health Organization for use as a standard method for assessment of bleeding and spotting episodes, particularly in research studies on the breakthrough bleeding associated with the use of progestin-only contraception (reviewed in Salamonsen et al., 1999).

Importantly endometrial repair (re-epithelialization) occurs simultaneously with tissue breakdown in a piecemeal fashion. This ensures that the endometrial “wound” is not open for days at a time but rather is essentially rapidly repaired at a similar rate to which it is shed. Menstruation is generally complete within 4–5 days and remarkably among adult tissues, repair occurs without scarring.

Mechanisms of Endometrial Breakdown

Decidualization

Decidualization of endometrial stromal cells is an irreversible differentiation process that takes place gradually throughout the secretory phase of the menstrual cycle, reaching completion during the mid-late secretory phase of a woman's cycle. The parent stromal fibroblasts undergo a limited mesenchymal to epithelial transition (MET) to become decidualized cells; these are of quite a different phenotype to their parent cell. In menstrual cycles the extent of decidualization is limited, being initiated around the spiral arterioles, and then spreading, the extent of this spreading being very variable between women and between cycles. In a conception cycle, however, decidualization spreads throughout the entire endometrium and these specialized cells provide the decidual component of the placenta. Initially, decidualization is driven by rising progesterone levels in the secretory phase of the cycle, acting via cyclic AMP, but regulatory factors (such as interleukin (IL)-11, and activin A) produced by the already decidualized cells and acting via diverse intracellular pathways create a cascade of differentiation, enhancing the process in adjacent cells. Furthermore the decidualized cells are also a major endometrial source of chemokines which are leukocyte chemoattractants, and are proposed to provide the initial stimulus for the leukocyte influx associated with menstruation. Importantly, the decidualized

cells are the major sensor of progesterone withdrawal; they are the only endometrial cell type to retain expression of the progesterone receptor in the mid-late secretory phase. Because the decidualized cells are terminally differentiated and cannot revert to their fibroblastic phenotype, menstruation and regeneration of the endometrial functionalis layer is necessary.

Progesterone Withdrawal

The Inflammatory Response

In the mid 1980's, Finn (1986) proposed that menstruation could be viewed as an inflammatory process since it shared the features of tissue edema, the presence of decidual cells resembling granulation tissue fibroblasts, and an influx of a remarkable number of inflammatory cells. Increased knowledge of inflammatory events and tools to examine these in detail, have strongly supported and extended this proposal. For example, mice lacking the progesterone receptor have a highly inflamed uterus, with considerable infiltration of leukocytes, while in cell culture studies, progesterone inhibits production of matrix metalloproteinases (MMPs) but withdrawal of progesterone from decidualized endometrial stromal cells increases production of MMPs, and members of the plasminogen activator family (Henriet et al., 2012).

Cytokine and chemokine release

The first phase of menstrual events occurs in the decidualized stromal cells, which express progesterone receptors and hence act as sensors of progesterone withdrawal. This initiates a sequence of inter-dependent events of an inflammatory nature, with intracellular responses identified within the decidualized cells. With progesterone withdrawal there is a decrease in cytoplasmic I-kappaB and a progressive increase in NF-kappaB which accumulates in the nucleus. Concomitant with this nuclear translocation, production of a host of inflammatory mediators, including cytokines and chemokines increases [interferon (IFN) α ; IL-6; CCL11; granulocyte-monocyte colony stimulating hormone (GM-CSF); CCL2; IL-1ReceptorA; CXCL10; CXCL8; IL-12; IL-15; vascular endothelial growth factor (VEGF) and CCL5]; this increase is blocked by an NF-kappaB inhibitor. Together these mediators can recruit inflammatory leukocytes into the premenstrual endometrium (Fig. 1).

Prostaglandins and related mediators

In addition, withdrawal of progesterone from decidualized cells upregulates prostaglandin G/H synthase 2 (PTGS2, also known as COX-2) signaling, along with the enzymes prostaglandin (PG)E synthase, PGI synthase and others, resulting in production of the pro-inflammatory prostaglandins PGF2alpha, PGE2, PGI2 and TXA2. Their related receptors are also elevated at menses, with at least the PGF receptor being increased via NF-kappa B activation (Evans and Salamonsen, 2012).

Reactive oxygen species and superoxide dismutases

Reactive oxygen species (ROS) and their scavenging enzymes, the superoxide dismutases (SOD) participate in a dynamic relationship in the endometrium. Since the ROS (which include superoxide radicals, hydroxyl radicals and hydrogen peroxide), are produced as by-products of normal metabolism, they must be kept in check by SOD (in three forms, Cu-, Zn-SOD in cell cytosol and Mn-SOD in mitochondria) which provide the first cellular defense against the cytotoxic actions of ROS. SOD are present in both glands and stroma throughout the cycle, and in vitro decidualization of stromal cells increases Cu-, Zn-SOD and Mn-SOD. However, their activity is significantly decreased just prior to menstruation. In decidualized stromal cells in vitro, Cu- and Zn-SOD decrease with removal of hormonal control, providing a potential mechanism for their loss of regulation at menstruation (summarized Evans and Salamonsen, 2012).

Fig. 1 The menstrual cascade: a process of controlled inflammation and tissue breakdown. Filled arrows represent the cascade, open arrows represent potential targets for restraint.

Leukocytes

The leukocyte population within the endometrium exhibits dynamic changes throughout the menstrual cycle. Leukocytes are present in the endometrium in only small numbers during the proliferative phase of the cycle, with an increase in natural killer cells and macrophages associated with the 'receptive phase'. During the secretory phase of the cycle, progesterone has antiinflammatory properties and its dramatic withdrawal during the late secretory phase leads to a massive influx and activation of inflammatory cells, particularly the granulocytes (mast cells, neutrophils, eosinophils, and basophils) which can release factors stored intracellularly in granules, but also monocytes/macrophages and uterine natural killer cells. These inflammatory cells can comprise up to 50% of the total cells in peri-menstrual endometrium. Leukocytes within tissues have constantly changing phenotypes and responses to paracrine stimuli which are difficult to define in tissue sections which represent only a snapshot in time (Evans and Salamonsen, 2012). The activation status of the granulocytes is critically important as they only become functional once activated, resulting in the release of their contents (rich in enzymes and cytokines) into the local tissue. Such activation has been demonstrated for both mast cells and neutrophils within menstrual tissue (Fig. 2). Due to the dynamic nature of the cascade of events involved in menstruation and the difficulties inherent in studying the processes involved, the roles of individual menstruation-associated leukocytes and their molecular mediators in women are not well defined. However, studies in mouse models indicate that functionally, neutrophils (Kaitu'u-Lino et al., 2007a) and macrophages (Cousins et al., 2016) are more important in repair than breakdown—whether this also applies in women, remains to be established.

Extracellular Matrix Breakdown

MMPs are the major class of enzymes responsible for breakdown of extracellular matrix (ECM): they can also activate or deactivate other enzymes and regulatory molecules such as chemokines and cytokines by proteolysis or cleavage of proteins from a latent to an active form. Most MMPs are released in latent forms and require extracellular activation by proteolytic removal of their pro-peptide. During the normal menstrual cycle, MMPs mRNA and protein are variable and at very low levels in the endometrium, but there is a dramatic increase immediately prior to and during menses. The natural tissue inhibitors of matrix metalloproteinases (TIMPs) that bind the active enzymes with 1:1 stoichiometry and hence inactivate them, are also locally present, with only minor changes during the cycle. It is only when the activated MMPs are in excess over the TIMPs that they can act to degrade ECM molecules: each MMP has an individual cohort of specific ECM that they can degrade. Importantly, cleavage of the native collagen fibrils which predominate within the endometrium, is restricted to specific proteases, the collagenases MMP1 and MMP8. Other MMPs can degrade the additional ECM molecules and the already cleaved fragments of native collagen: these include MMP2, MMP3, MMP7, and MMP9. All of these enzymes are present and active during menstruation, when they are induced both by progesterone withdrawal and also by locally produced cytokines such as IL-1 α . A pivotal role for MMPs in ECM breakdown at menstruation has been clearly

Fig. 2 Activation of granulocytes is required for their functionality. Shown here is mast cell tryptase staining (red) in day 1 menstrual tissue, (A) an inactive mast cell, (B) an activated mast cell which has released tryptase into the surrounding tissue, (C) lower power of B, showing the extent of tryptase release. Reprinted from M. Jeziorska et al. (1995). *Biology of Reproduction* 53, 312–320 with permission.

demonstrated both *ex vivo* and in endometrial explants. MMPs-1, -2, -3, -8, -9, -10, and -11 are predominantly produced by endometrial stromal cells while MMP1, -2, -3, and -9 are also expressed by endometrial vascular cells and MMP2, -7, -9, and -26 by epithelial cells. Importantly specific MMPs are also present in the infiltrating leukocytes at menstruation. It is now clear that MMP release and activation occurs in a cascade of events at menses: for example, pro-MMPs produced by stromal, epithelial and vascular cells can be activated by enzymes including neutrophil elastase, the mast cell enzymes chymase and tryptase, members of the kallikrein family, and by other MMPs such as MMP3 which is produced by stromal fibroblasts (review [Henriet et al., 2012](#)). The enzyme activities are very carefully controlled: fluorescent visualization of active MMP2 and MMP9 in menstrual tissue sections showed precise spots of activity throughout the tissue rather than the much wider activity observed using the same technique in cancers. This demonstration of specific foci of degradation enzymes supports the histological findings that menstrual breakdown is not a synchronized shedding of the whole tissue at a single time. Rather, tissue shedding initially occurs at very focal points, spreading across the tissue with time. Indeed a single histological section of menstrual tissue may contain intact decidualized tissue alongside areas of both breakdown and repair, highlighting the complexity of this tissue and the piecemeal nature of this tissue breakdown.

Vascular Events

While the very early studies on menstruation suggested that it results from a physiological ischemia-reperfusion injury, whether or not hypoxia is truly present in menstrual endometrium and involved in the menstruation process is still under debate. Work in a range of models indicates that hypoxia is not essential for either endometrial breakdown or repair although it may promote these processes ([Maybin and Critchley, 2015](#)). However, the vasculature clearly plays a role in the menstrual cascade and the balance of vasoconstriction versus vasodilation during menses will contribute to the extent of blood loss. At least two vasoconstrictors, PGF2 α and endothelin (ET) 1, are implicated in heavy menstrual bleeding (HMB). Highly potent ET1 is decreased in concert with an increase in its metabolizing enzyme neutral endopeptidase in women with HMB, with a similar decrease seen in the PGF2 α (vasoconstrictor)/PGE (vasodilator) ratio. Differences in spiral arteriole maturation may also contribute to the extent of vasoconstriction at menses, with vessel wall circumference, focal discontinuities, and reduced vascular smooth muscle myosin heavy chain (a marker of maturation) all altered in women with HMB. Menstrual disorders, including HMB are discussed in detail elsewhere in this series.

Endometrial coagulation

Cessation of menstruation requires an intact endometrial coagulation system. Indeed, HMB is reported by a majority of women with the inherited bleeding disorder, von Willebrand's disease, and this considerably impairs their quality of life. Von Willebrand factor interaction with platelets is one of two mechanisms resulting in a hemostatic plug; the other mechanism involves tissue factor generation of thrombin and the subsequent formation of fibrin via the coagulation cascade. Most of the components of this system are present in human endometrium (tissue factor, tissue plasminogen activator (tPA) its inhibitor (PAI-1), urokinase (u)PA, and the uPA receptor-1. PAI-1 and tissue factor are reduced by progesterone withdrawal, thus promoting menstrual bleeding. Evidence also exists for over-activation of the fibrinolytic system in women with HMB: indeed, the successful use of the hemostatic agent, tranexamic acid, as a treatment for HMB, provides strong evidence for such fibrinolytic over-activation as a driver of excessive bleeding (reviewed [Schatz et al., 2016](#)).

Mechanisms of Endometrial Repair

The shedding of endometrial tissue at menstruation is very carefully controlled: the lower third of the functionalis and the entire basalis layer generally remain, and it is from these maintained areas that endometrial repair occurs. However, it is clear that repair can occur from even tiny foci of residual tissue as the endometrium can become fully restored following extensive surgical curettage or ablation and indeed, it is almost impossible to create an endometrial-free uterus by surgical means. Electron microscopy and histology, have demonstrated clearly that re-epithelialization and repair of the endometrial surface are in progress as early as day 2 of menses in areas denuded of tissue, even while active proteolysis is occurring in adjacent areas of the endometrium ([Ludwig and Spornitz, 1991](#)). Indeed, in tissues obtained on day 2 of menses and even later, areas of active lysis are observed alongside both repairing tissue and decidualized tissue remaining from the previous cycle in histological sections ([Gaide Chevronnay et al., 2009](#)). However, to date, the mechanisms of endometrial repair are less well defined than those of menstrual breakdown at least in part because the two are proceeding concurrently.

As evidenced from the study of ovariectomised women and women in natural menopause, ovarian estrogen is not required for endometrial repair/re-epithelialization. Further, a mouse model in which all possible sources of estrogen were removed (even that from fat and food), demonstrated normal progress of repair progresses after induced menses ([Kaitu'u-Lino et al., 2007b](#)). However, estrogen is clearly needed for subsequent growth and regeneration of the endometrium during the proliferative phase of the cycle. The separate process of estrogen dependent tissue regeneration is reliant on initial re-epithelialization; studies in the mouse suggest that the stromal compartment does not become responsive to ovarian steroids until re-epithelialization is complete ([Bigsby, 2002](#)) and proliferation is not observed in the human endometrium until day 5–6 when a fully epithelialized surface is present (reviewed [Maybin and Critchley, 2015](#)).

Since endometrial repair occurs in a piecemeal manner, simultaneously with breakdown, the microenvironment in its early stages of re-epithelialization is highly inflammatory. However, once the inflammation is resolved, restoration of the full cellular

cohort and thickness of the functionalis, requires angiogenesis, glandular development, ECM formation and tissue remodeling and these are not complete until late in the proliferative phase of the endometrial cycle.

Importantly, repair of the endometrium is completely ‘scar-free,’ unusual among adult tissues. Thus while postmenstrual repair has commonalities with restoration of wounds in other tissues, there are also important differences which could, when fully understood, have significant translational benefits beyond the endometrium.

Re-epithelialization

Very rapid re-epithelialization is needed to cover the endometrial surface; it stops the bleeding and enables subsequent regeneration of the stromal compartment. It is observed as early as day 2, and occurs during active bleeding. Thus, repair occurs within a micro-environment of menstrual fluid which contains many proteins not found in peripheral blood. Menstrual fluid itself, and a number of these unique proteins within the fluid, stimulate re-epithelialization of wounded human endometrial epithelial cell monolayers in vitro primarily by promoting cellular migration (Evans and Salamonsen, unpublished). This strongly supports the contention that the very rapid re-epithelialization arises from retained epithelial luminal or glandular cells as initially indicated by scanning electron microscopy of menstrual endometrium (days 2 to 6) (Ludwig and Spornitz, 1991), in which re-epithelialization appeared to be initiated by cell migration from the mouths of open glands. However, more recent combined histologic and hysteroscopic studies, suggest that at least some of the epithelial cells may arise from MET of stromal cells (Garry et al., 2009). The exposed stromal surface following shedding is covered with a fibrinous matrix, upon which new epithelial cells were observed either as single cells or in small groups, not associated with the glandular stumps and it is these that are proposed to arise from the stromal compartment. However, these findings still require independent validation. The MET required for stromal fibroblasts to transition to the epithelial phenotype is commonly observed at least in part, during decidualization during which the fibroblasts become ‘epithelioid’. However, to form true epithelial cells the transformation would need to proceed further to include induction of junctional complexes and formation of tight baso-lateral connections, not observed in decidual cells. Nevertheless, since both proteins and genes known to be involved in MET are present during menstruation (reviewed Maybin and Critchley, 2015), it is possible that epithelial cell migration and MET occur simultaneously. Endometrial leukocytes are also present during repair. Indeed, in mouse models, both neutrophil and macrophage depletion reduces endometrial repair: emerging evidence indicates that at least the macrophages differentiate into repair-specific phenotypes within the tissue. How these cells promote or participate in endometrial repair is still to be determined.

Revascularization

Concomitant with re-epithelialization, restoration of the circulation is essential to maintain endometrial survival. As visualized by scanning electron microscopy, transverse endometrial arterioles in the subepithelial stroma and the ascending spiral arterioles are torn open as the tissue is shed (Ludwig and Spornitz, 1991; Garry et al., 2009). While such vessels will eventually fully regenerate, there is a need for very rapid repair of vascular integrity to minimize the risks of hemorrhage. A number of vascular repair agents including VEGF are present during menses (see above). Indeed, VEGF is produced by in vitro decidualized stromal cells after hormone withdrawal; this and other factors likely play key roles in rapid vascular repair. Additional factors, most likely reliant on estrogen action, are expected to drive subsequent slower vascular development during the regenerative proliferative phase.

Regeneration

Small populations of adult stem/progenitor cells with classic stem cell properties have been identified in human endometrium and proposed to contribute to the ability of the endometrium to regenerate during each menstrual cycle (Gargett et al., 2016). These include epithelial progenitors, mesenchymal stem cells and side-population cells. The epithelial progenitor cells which are located in vivo in the basalis layers of the endometrial glands, can differentiate into gland-like structures. Appropriately, the mesenchymal stem cells are detected peri-vascularly in both endometrial functionalis and basalis. It is not yet clear whether in vivo, one or more stem/progenitor cell type regenerates endometrial tissue. However, it is most likely that epithelial outgrowth is initially needed to rapidly cover the wound, with regeneration from stem cells contributing to the subsequent development of multicellular full thickness tissue.

Conclusions

Understanding how the menstrual endometrium limits inflammation, modulates immune cell activity, rapidly repairs and remains scar free, all within a 4 to 5 day time-frame, has implications for the development of treatments for a number of endometrial pathologies including abnormal uterine bleeding, Asherman’s syndrome and endometriosis. Furthermore, understanding processes within this dynamic reproductive tissue has widespread implication for understanding and treating pathologies in other organs. Skin wounds, for example, commonly exhibit deficient re-epithelialization, burn wounds often repair with massive scarring, while diabetic wounds can persist for months. Given that the inflammation associated with menstruation is highly controlled, translation of these regulatory mechanisms could also lead to novel therapies for resolution of chronic inflammation. Regrettably, since discussion of ‘menstruation’ is not well accepted socially and also carries cultural taboos, progress on its understanding has been slow, in spite of the many women who suffer menstrual abnormalities and the broader contributions that this could provide.

Glossary

Bicornuate Having two horns; here the context is the mouse uterus, a v-shaped organ fused at the two cervixes.

Deciduochoorial placenta The boundary between maternal and conceptus-derived tissue is between placental trophoblast and maternal uterine decidua. Seen in the first trimester of human pregnancy.

Hemochorial placenta The interface is between syncytiotrophoblast at the outer surface of the placenta, and maternal blood. Occurs in the second and third trimesters of human pregnancy.

Proliferative phase Period of about 10 days after menstruation ends, during which the endometrium regrows from a thin basal layer.

Secretory phase Period of about 2 weeks during which the endometrium undergoes changes that allow it to accept and support an implanting embryo, if fertilization has occurred.

Anatomy

The uterus comprises a mucosal lining, the endometrium, and outer muscle sheath, the myometrium, enclosed in a serosal (perimetrial) layer. Both are targets of steroid hormone action. In human and many primates the uterus has a single corpus connected via two fallopian tubes to the right and left ovaries. During pregnancy, the organ expands with growth of the conceptus, and the endometrium and myometrium become thinner.

The vascular supply to the uterus is from the ovarian artery and the descending aorta. In human there are two uterine arteries running laterally in a cephalocaudal direction. In bicornuate species such as mouse and rat the vascular supply is from a central (mesometrial) plexus emanating from a single uterine artery. Arcuate (circumferential) arteries connect the uterine artery to a series of radial arteries, which in turn supply spiral arteries that become arterioles in the endometrium. They feed a substantial capillary plexus that surrounds glands and opens into wider channels near the tissue surface. Close to a doubling of flow through the uterine artery occurs during the second half of pregnancy in women, its diameter increasing apparently in response to estrogen. The spiral-shaped arteries in the inner myometrium and endometrium produce increased impedance in the circuit, possibly as a way of protecting the implanting embryo. During pregnancy, spiral arteries are remodeled to allow a low pressure, high volume flow through the placenta.

The Non-Pregnant Endometrium

The uterine lumen is lined by a simple cuboidal surface epithelium, opening into tubular glands that extend radially, ending at the junctional zone with the myometrium. Glands are also lined by a single-layered epithelium that varies from columnar to cuboidal in women. Beneath is stromal tissue containing mesenchymal and immune cells, blood vessels and nerves all set in a collagenous extracellular matrix. The junctional zone is a discrete layer, visible by ultrasound or magnetic resonance imaging.

Menstrual and Estrous Cycles

Between menarchy and menopause, women normally experience about 400 menstrual cycles in response to changing levels of ovarian hormones. There is a gradient of hormone responsiveness in endometrial tissue: the upper functionalis (about 80% of the tissue depth at mid cycle) undergoes marked histological changes, while the basalis exhibits more subtle alterations. Over three quarters of the endometrial lining is lost at menstruation, leaving a thin basalis from which scar-free regeneration occurs. The ensuing proliferative phase equates to the follicular phase in the ovary. Regeneration is stimulated by ovarian estradiol (E2), the endometrium growing from <2 mm (**Fig. 1**) to 7 mm by the end of the proliferative phase. Within 2 days of the end of menstruation, epithelial cells migrating from gland openings have recovered the tissue surface with a new luminal epithelium. The tissue thickens under the influence of estrogen, glands elongate, stromal cells proliferate and produce an abundant collagenous extracellular matrix, and angiogenesis restores the vascular network.

In the late proliferative phase, luteinizing hormone (LH) levels rise to a peak, and progesterone production is initiated in the follicle. Ovulation occurs, and progesterone (P4) and E2 from the corpus luteum act together on the endometrium, which now enters its secretory phase with onset of cell differentiation and a reduction in proliferative activity. Initially the effects are most prominent in the glandular epithelium, which starts to amass glycogen in subnuclear cytoplasmic masses (early secretory phase).

Fig. 1 Uterine histology in the menstrual cycle. *Left and centre*, proliferative phase showing endometrial luminal epithelium and tubular glands above myometrial tissue containing spiral arteries. *Right*, late secretory phase endometrium. H&E staining.

An unusual spherical stack of interdigitating tubules known as the nucleolar channel system (NCS), is present in 5% of epithelial cell nuclei in the mid-secretory phase. Enlargement of epithelial mitochondria occurs. In the mid secretory phase epithelial cells start to release secretory substances, filling the gland lumens. Ciliated epithelial cells, which are prominent at the necks of glands and are at a maximum at this time, waft the secretions into the uterine lumen. Secretions persist into the late secretory phase (**Fig. 1**).

In the mid secretory phase, areas of edema appear in the stroma, indicating ECM remodeling. Arterioles in the functionalis elongate and assume the characteristic spiral form. In proliferative phase, lymphoid aggregates form in the endometrial basal; these contain T and B cells which disperse later in the cycle. T_{reg} cells, macrophages, dendritic cells and mast cells are also present. Further immune cells, particularly uterine natural killer cells, are recruited later in the cycle.

The mid secretory phase represents a nodal point. If fertilization occurs, the CL is rescued by the conceptus as described below. Progesterone levels rise and the endometrial stroma begins to differentiate. If not, steroid levels reach a maximum about a week after ovulation, and then decrease, leading to menstruation.

Sex Hormones and Their Receptors

The actions of the sex steroids in the endometrium occur largely as a result of binding to their cognate nuclear receptors, estrogen receptors (ER α and ER β) and progesterone receptor (PGR, with splice variants A and B), which are transcription factors. Many, but not all, cells in the endometrium express these receptors. In addition there are “non-classical” receptors at the cell surface: for estrogen, a variant of the nuclear estrogen receptor and a G-protein-coupled receptor; for progesterone, members of the PGRMC and membrane progesterone receptor (mPR) families. Cell surface receptors mediate more rapid responses to steroidal stimulation that do not depend on changes in transcription.

Some steroid effects require paracrine actions between cell populations in the 3D tissue environment, and there is clear evidence for bidirectional communication between epithelial and stromal cells, both in the non-pregnant cyclic and at implantation. Some description is included below but the scope of this article does not permit a detailed account.

ER α and ER β are encoded by two distinct genes. ER α is the predominant isoform expressed in the endometrium, and ligand binding stimulates proliferation in gland and stromal cells during the proliferative phase, with a steep decline in the secretory phase. Signaling through the phosphoinositide 3-kinase/protein kinase B (PI3K/AKT) pathway and hyperphosphorylation of retinoblastoma (Rb) and p107 proteins activate the DNA replication machinery for S-phase entry. In laboratory rodents, E2 stimulates epithelial proliferation by means of a paracrine pathway in which binding to stromal ER α leads to production of FGF, in turn driving epithelial proliferation by activating extracellular signal-regulator kinase (ERK) 1 and 2 or PI3K/AKT. Persistent ER α expression in epithelial cells may help them avoid apoptosis. The same may well be the case in human, as most endometrial epithelial cells rapidly cease proliferation in vitro, that is, in the absence of stroma.

A further important action of E2 is to induce PR in endometrial cells. During the secretory phase, P4 counteracts the mitogenic effects of E2 and stimulates stromal differentiation and the secretory function of the glands. Ablation of murine PR results in a hyperplastic response to E2 and P4 in epithelium. The anti-proliferative actions of P4 on the epithelium are mediated by down-regulation of ER and induction of 17 β -hydroxysteroid dehydrogenase Type 2, which catalyzes the conversion of E2 to estrone, which is less active. Other contributory mechanisms include a paracrine interaction in which the transcription factor HAND2 is induced in the stroma, and suppresses FGF expression.

PRA and PRB are splice variants of the receptor. PRA predominates in the endometrium. However, after ablation of murine endometrial PRA, epithelial proliferation is retained upon P4 treatment, and this response is dependent on PRB. Epithelial PR also affects stromal function: the selective knockdown of epithelial *Pgr* in mice results in infertility with failed decidualization.

Other cells in the endometrium that express steroid receptors include vascular endothelial cells (PRB, ER) and uNK cells (PRB).

Menstruation

In mid to late secretory phase, progesterone exerts an anti-inflammatory effect on the endometrium. Stromal cells that have been exposed for over a week to P4 begin the characteristic changes known as decidualization, which is discussed in “**Decidualization**” section. Decidualising endometrial stromal cells express tissue factor, which can activate the clotting cascade if interstitial leakage of plasma occurs. The steep decline in progesterone in late secretory phase leads to a reduction of Cu/Zn superoxide dismutase and loss of protection against oxidative damage. As a result, I κ B is degraded and its inhibition of NF- κ B lifts. NF- κ B moves into cell nuclei and binds to the progesterone receptor, adding to effective progesterone withdrawal. It activates production of the enzyme cyclooxygenase 2 (COX2), which catalyzes the synthesis of prostaglandins E2 and F2 α ; PGF2 α is vasoconstrictive, while PGE2 increases vessel leakage. Endothelin (ET-1) increases, adding further to vasoconstriction. Spiral arteries, a key locus of control of menstruation, are the main target for these actions. These vessels are unique to the human/primate endometrium and are highly sensitive to progesterone. They are controlled by perivascular cells (smooth muscle and pericytes).

Another action of nuclear NF- κ B is to upregulate transcription from genes encoding a large repertoire of pro-inflammatory cytokines and chemokines. Chemokines, produced initially by stromal cells, recruit inflammatory cells—neutrophils, monocytes and eosinophils—from circulation. Mast cells are activated. Inflammatory cells and resident epithelial and stromal cells produce a repertoire of matrix metalloproteinases (MMPs) which, following extracellular activation, proceed to break down ECM to destabilize the functionalis. Glands collapse, acquiring a serrated appearance. Plasminogen activator levels increase to digest fibrin, and tissue breakdown leads to shedding of approximately the upper two thirds of the endometrium, including most of the functionalis. Vessels constrict to limit bleeding, and locally available tissue factor triggers clotting.

Vascular constriction results in ischaemia and hypoxia in the tissue; in turn this switches on hypoxia-activated factor 1 (HIF1 α), a transcription factor that activates a set of downstream genes required for postmenstrual regeneration. One of these is vascular endothelial growth factor (VEGF), which is important for regeneration of blood vessels. Inflammatory cell phenotypes, especially in macrophages and neutrophils, shift from pro- to an anti-inflammatory, and these cells produce other growth factors that contribute to regeneration.

Menstruation occurs in rather few species: human, a few other primates and certain bats. The cascade of events that initiates and then controls menstruation in non-conception cycles depends on the presence of decidualised stromal cells. This is nicely demonstrated in the mouse, where decidualization occurs in steroid-sensitized stroma only when a stimulus is received from the implanting embryo. In this species, experimental withdrawal of steroid produces a much steeper decline in circulating levels than in the normal estrous cycle. This triggers menstruation, but only if the stroma has already initiated decidualization. In non-menstruating species, tissue remodeling occurs as the corpus luteum regresses at the end of the estrous cycle, and this is achieved without shedding of endometrium.

Progenitor and Stem Cells and Renewal of Endometrium

Based on growth in vitro of clones from single cells, there is a population of stromal progenitor cells (~1%) as well as a smaller (~0.2%) epithelial reserve population (CD44+/label-retaining and clonogenic in vitro). The stromal cells seem to reside in vivo in a peri-vascular location based on their marker expression profile CD146(+)/PDGFR β (+)/SUSD2(+), and they are probably drawn from the pericyte population. Though the endometrial basalis is normally expected to act as a reservoir of tissue from which post-menstrual regeneration can occur, both epithelial and stromal clonogenic cells can be recovered from functionalis tissue sampled using, for example, a pipelle suction device. They are of interest in the context of endometrial proliferative disorders such as adenomyosis and Asherman's syndrome, as well as in the establishment of endometriotic lesions from tissue shed at menstruation and refluxed through the fallopian tubes.

Though most of the cells of the functionalis at full thickness are probably derived by activation of cells resident in the basalis into cycles of proliferation, there is evidence that some can be recruited from cells in circulation. Women who have had blood or bone marrow transplants carry donor cells that can be recognized by virtue of their histocompatibility antigens at the cell surface. Such cells can be found in endometrium several years after transplantation, and they contribute to both stromal and epithelial cell compartments. In mice, similar observations have been made after transplantation of fluorescent-tagged bone marrow cells, indicating that this process occurs even in a non-menstruating species.

Pregnancy

There is remarkable inter-species diversity in placental form, with deep or superficial implantation and from one to many offspring. Comparative genomic analysis suggests that the placenta has evolved in response to constraints imposed by the maternal uterine environment.

Initially the hatched blastocyst attaches to the endometrial luminal epithelium. This may result in a long-lived adhesive interaction, as required in epitheliochorial placentation (e.g., in pig, sheep and cow). Here the conceptus is retained in the uterine lumen for the duration of pregnancy and nutrients are transferred from maternal capillaries across the luminal epithelium to apposed or adherent trophoblast. In interstitial implantation (human (**Fig. 2**) and laboratory rodents) attachment to the luminal epithelium is followed rapidly by invasion of the underlying stroma.

In mice and rats, implantation induces a transient increase in vascular permeability that is dependent on P4 binding to PR in venous endothelium, where it activates another transcription factor, NR4A1 to initiate a relaxation in the barrier function of the vessel wall.

Fig. 2 The Falkiner embryo: secondary villous stage, about day 27 from the last menstrual period. Blue represents the embryo (bilaminar disc stage) and placenta (secondary villus stage; blue). Maternal tissue is colored mustard. Note the highly glandular, hypersecretory decidua beneath the embryo. Decidua has extended over the implant, encasing it. Trophoblast invasion has begun but the cells are not colored as this was not recognized at the time of publication. Reprinted with permission from Falkiner, N. (1932) *British Empire Journal of Obstetrics and Gynecology*, **39**(3), 471–506.

Rescue of the corpus luteum is effected in human by chorionic gonadotrophic released by trophoblast, which travels to the ovary and binds the LH receptor. Only primates and equids produce CG, and there are many alternative mechanisms of CL rescue in the animal world. For example, mice use prolactin, while in ruminants, trophoblast-derived interferon tau binds to the luminal epithelium, initiating a signaling cascade that blocks its production of luteolytic prostaglandin F2 α .

Decidualization

Decidualization is a process of stromal differentiation that is confined to species in which embryo implantation occurs interstitially, creating an interface between trophoblast and the maternal uterine stroma.

In women, decidual cells start to appear at the mid-secretory-late secretory transition, about day 23 of the cycle. It is notable therefore that implantation occurs in human *before* decidual changes have been initiated in the endometrial stroma; though there are few direct observations of these stages, decidualization is probably initiated 1–3 days after trophoblast starts to penetrate the stroma. Decidual cells arise by differentiation of resident stromal cells in response to a prolonged exposure to progesterone, with binding to PRA leading to receptor phosphorylation, dissociation from chaperone proteins, dimerisation, binding to response elements in specific genes, recruitment of coactivators and finally transcription. The resultant chromatin reorganization and genome-wide alteration of histone modification give rise to a profoundly distinct repertoire of gene expression.

Elevation of intracellular cAMP is also required for decidualization, and is achieved by stimulation of several G-protein coupled receptors leading to adenylyl cyclase activation and, in turn, the activation of cAMP-dependent protein kinase A which acts on targets in the cytoplasm or nucleus. Extracellular ligands involved in the initiation of this cascade include the prostaglandin PGE₂, hCG, LH, follicle stimulating hormone (FSH), and corticotropin-releasing hormone (CRH).

In addition, a discrete subfamily of genes is activated by androgen binding to its receptor in cells undergoing decidualization; this may be required for cytoskeletal reorganization leading to morphological change. The cells enlarge, accumulate fat and glycogen granules, acquire a distinct polygonal shape, and begin to produce a characteristic repertoire of secretory substances including prolactin and insulin-like growth factor binding protein 1 (IGF-BP1). They express a repertoire of antioxidant enzymes including glutathione peroxidase (GPX) 3, monoaminoxidase A, superoxide dismutase (SOD) 2, glutathione transferase, peroxiredoxin 4 and thioredoxin, and as a result are resistant to DNA damage and cell death induced by reactive oxygen free radical species.

Not all stromal cells decidualise; the characteristic morphological changes are initially seen most prominently in cells near spiral arterioles and beneath the luminal epithelium. There is evidence for a periarteriolar niche that contains a discrete subpopulation of cells (~5% of the stromal population) that may contribute to regeneration after pregnancy. They bear the surface protein Sushi domain containing 2 (SUSD2) and express vascular-related genes such as ELN (elastin), MYH11 (myosin 11) and α smooth muscle actin, as well as NOTCH3 and the niche cell marker MCAM (CD146). A few per cent are clonogenic *in vitro*, while the SUSD2-negative population contains at least 10 times fewer clonogenic cells. *In vitro* cells can shift from SUSD2-positive to negative and vice versa, and both can decidualise *in vitro* under a standard stimulation protocol. However, positive cells respond to decidualization by enhanced production of a group of immunomodulators and trophic factors. Stromal cells are apparently sensitive to local community signaling, cooperating to achieve a tissue-level biological end point by diversifying within a phenotypic envelope characteristic of the specific environment. The reappearance of SUSD2+ cells after menstruation or pregnancy probably relies on the re-creation of a permissive periarteriolar niche during regeneration.

Decidualization initiates reorganization of extracellular matrix in the functionalis. Basement membrane components including collagen IV and laminin are produced (Fig. 3), and in human are elaborated into a pericellular basement membrane in cells that have undergone the classical morphological transition into large polygonal shapes. These cells are probably sessile, while other cells may remain motile, allowing the space above the implanting embryo to be repaired and infilled by stroma with a covering

Fig. 3 Decidua in human first trimester pregnancy. *Left*, laminin (brown staining) in the pericellular basement membrane of decidualised stromal cells (a few examples are labelled (*)). *Centre*, glands and a spiral artery in hypersecretory decidua spongiosa beneath an implanted embryo, 5th week. *Right*, gland in compact decidua parietalis in the first trimester. Note the adjacent stromal inflammatory infiltrate. The scale bar (*left*) represents 25 μm at left, 650 μm in the center, and 50 μm at right.

epithelium. Active turnover of the major fibrillar collagens (types I, III and V) occurs; if the MMP inhibitor TIMP1 is overexpressed in stromal cells in the mouse, the extent of decidualization is reduced, and the embryo is displaced mesometrially with less stringent control of its orientation. Type VI collagen, which forms microfibrils that wrap around and stabilize the organization of the major fibrillar components of the ECM, is lost from most of the stroma, but is retained around blood vessels. The looser ECM probably has the capacity to expand to accommodate the implanting embryo. In addition ligands such as laminin in the decidual ECM (Fig. 3) engage integrins at the surface of trophoblast to promote invasion. In this context it is instructive that implantation fails in mouse embryos lacking the beta1 integrin subunit, which pairs with numerous different alpha subunits to form a family of surface receptors for ECM ligands; the embryos cannot progress beyond the initial breach of the epithelium.

As discussed in “Menstruation” section in the context of menstruation, decidual cells play an important role in initiating and controlling inflammation in the endometrium. At the same time, immunological management is required to ensure survival of the fetal allograft. This is not achieved by means of wholesale immune suppression, rather immune recognition of the placenta is required, with both local and systemic adjustment of the immunological environment. Trophoblast interaction with the innate immune system via uterine NK cells is one element in this process. Regulatory T cells are also important, indeed mice lacking T_{regs} are infertile. Stromal cell decidualization may therefore have evolved to manage the specific inflammatory and immune processes associated with invasive implantation. In some eutherians, decidual cells are lost after the implantation phase of pregnancy, indicating they are not required for the maintenance of these complex relationships.

In mouse and rat, decidualization of the uterine stroma requires steroid hormone priming, but is dependent on the presence of an embryo in the uterus. In these species the maternal tissue closes in to create an implantation chamber, a crypt-like branch off the main luminal axis. Decidualization is initiated by a signal from the embryo transduced by the epithelium to the underlying stroma, beginning in the superficial antimesometrial area and spreading deeper and towards the mesometrial pole. In these species (unlike in human) invading trophoblast encounters decidual cells as soon as the epithelium is breached. Steroid-sensitized uterus can also be stimulated to decidualise by means of a physical stimulus such as the instillation of oil or a superficial needle scratch to the luminal surface; this response is known as a deciduoma.

Embryo Selection and Correction

At least half of all fertilized human eggs are thought to fail to proceed to a clinically detectable pregnancy. One important reason is that embryos show a surprisingly high level of chromosomal abnormality, which arises in the first place from meiotic errors during gamete formation and secondly from errors in mitosis during pre-implantation development which, depending on the stage at which they occur, can give rise to different levels of genetic mosaicism. Abnormal embryos often develop the blastocyst stage, and may appear morphologically normal. Since some abnormal karyotypes (monosomies for example) are detected in preimplantation stage embryos but not in miscarriages, it has been hypothesized that the endometrium exercises a degree of quality control, to limit maternal investment in a compromised conceptus. In cows, where implantation is epitheliochorial (that is, the embryo remains positioned in the uterine lumen throughout pregnancy), gene expression in the endometrium differs depending in whether embryos were produced by in vitro fertilization, somatic cell nuclear transfer or artificial insemination.

Selection may occur at the stage of initial interaction with the epithelium: the apical glycocalyx, a protective mucin layer, has been suggested to act as a barrier, requiring an apposed embryo to send a signal to activate a process of clearance in order to advance to attachment and then breach the epithelium. In interstitially implanting species such as human, there is evidence for biosensing of embryo quality by decidual tissue, with suppression of supportive (e.g., growth-promoting) cytokines in the presence of an abnormal (e.g., developmentally arresting) embryo. This response, which requires the stromal cells to have decidualised, may arise after endoplasmic reticulum stress has been triggered. Decidualization also establishes an immune tolerant environment that might be overridden in the presence of an abnormal embryo. The incidence of mosaicism in human preimplantation embryos is so high that self-correction mechanisms are likely to exist; for example, karyotypically abnormal cells might apoptose or become segregated into the placenta.

Post-Implantation Development of the Placenta

Soon after implantation in human, rapidly growing cytotrophoblast occludes the superficial spiral arteries to that maternal blood cannot flow into the developing intervillous space. During this period (the first 11 weeks, coinciding with organogenesis) the placenta is very hypoxic, with an oxygen partial pressure of <20 mmHg at 8 weeks. By 12 weeks it has risen to >50 mmHg and protective antioxidant enzymes, such as catalases, GPXs and SODs have begun to be expressed in the placenta. Antioxidant enzymes in decidual cells offer protection for the developing placenta.

Meanwhile trophoblast invades more deeply, both into the decidual stroma and arteriolar walls. Changes to the arterioles are initiated by maternal uterine NK cells and macrophages, with disruption of the smooth muscle layers and endothelial hypertrophy, and the invasive trophoblast population collaborates in this process as it moves deeper through the decidua. Vascular smooth muscle is eventually replaced by trophoblast embedded in a fibrinoid extracellular matrix, so that the ability to respond to vasoconstrictors is reduced or lost.

At 11 weeks the trophoblast plugs are displaced and maternal blood can flow through the intervillous space. Thus the placental interface becomes hemochorial rather than deciduochorial. Trophoblast invasion progresses more deeply into the endometrium, crossing the junctional zone and continuing as far as the inner third of the myometrium. Spiral arterial segments are transformed to the corresponding level.

The idea that decidua may acts to restrain the invasion of trophoblast has gained traction from the genetics of imprinting. Imprinted genes are differentially expressed from their maternal and paternal alleles, a phenomenon found only in eutherian species. An example that has been explored in mouse is *igf2* (encoding insulin-like growth factor II), which is important in stimulating fetal growth. *Igf2* is expressed exclusively from the paternal allele, and imprinting theory interprets this as a paternal drive to produce larger offspring, which must be constrained by the mother so that her resources are not invested disproportionately in this offspring as compared with those arising in other pregnancies, and her continuing survival is secured. In turn, the gene encoding the recycling receptor *igf2* is imprinted with expression from the maternal allele, so the amount of available IGF is influenced by imprinting from the maternal side. Whether this applies to the uterine control of invasive trophoblast is unclear. However there is evidence in mouse that trophoblast does influence decidual gene expression: antimesometrial decidua differs in its gene expression signature from mesometrial decidua, arguably because the two are receiving paracrine signals from different populations of placentally-derived trophoblast.

Endometrial Glands in Pregnancy

In some species (though not human), endometrial glands form postnatally. In sheep and mouse this process has been inhibited by administering neonatal progestin. In both cases, the animals grow into infertile adults. Gland cell functions are therefore critical to fertility and pregnancy outcome. In the mouse, leukemia inhibitory factor (LIF) is released from glands in response to an estrogen pulse that occurs about 3 days after mating. It diffuses into the uterine lumen to activate receptors on luminal epithelium, producing a receptive state for embryo attachment.

In human, glands are important in the deciduochorial period, before maternal blood circulates in the intervillous space (Figs. 2 and 3). Glycogen stores in epithelial cells are broken down, with release of glucose oligomers into gland lumens. Glycoproteins and lipids are also present in gland secretions. These substances diffuse through narrow channels in the cytotrophoblast shell to reach the intervillous space, from where nutrient import can take place by villous syncytiotrophoblast. In this way they contribute

(with components of plasma and stromal secretions) to embryonic nutrition. From 11 weeks the placenta is predominantly hemochorial. In the second trimester, the gland cells regress to a flatter shape with reduced cytoplasmic contents and secretions.

Blood Flow in Pregnancy

From mid pregnancy, flow through the uterine artery increases steadily, as a result of NO-mediated relaxation resulting from stimulation of endothelial nitric oxide synthase by estrogen, and the effects of circulating relaxin. A larger volume of blood therefore enters the spiral arteries. However, remodeling has increased their diameter and abolished any contractile capacity, so following upstream relaxation, a high volume can traverse the intervillous space at low velocity, minimizing shear damage to placental villi (Fig. 4). Venous drainage channels are prominent at the periphery of the placental bed.

Uterus: Growth Factors and Cytokines

Introduction

Growth factors are a family of secreted signaling proteins that act in a paracrine and endocrine fashion to induce cellular proliferation and differentiation. Cytokines are polypeptide glycoproteins, which are produced in relatively small quantities and have a short half-life, restricting their sphere of influence to the local environment. Cytokines can promote or suppress multiple aspects of target cell behavior, impacting metabolism, stress response, survival, proliferation, and differentiation. Signaling via growth factors or cytokines is mediated by specific cell surface receptors. Across mammalian species, there is considerable similarity in the types of growth factors and cytokines that are expressed in the uterus, suggesting a high degree of conservation. In this article, we summarize the current understanding of the nature and role of growth factors and cytokines in the rodent and human uteri during the reproductive cycle and early pregnancy.

Uterine tissue is comprised of heterogeneous cell types. The cells lining the uterine lumen are epithelial cells. Subjacent to the luminal epithelium is the stroma, which harbors the fibroblastic stromal cells, endothelial cells, and a variety of immune cells. Dispersed within the stroma are glands, which are also lined by a single layer of epithelial cells. The cellular components of the uterus constitute the endometrium. The myometrium, defined as the outer layer of the uterus, houses the muscle cells. The focus of this article is the function of growth factors and cytokines produced by the endometrium. Secretion of cytokines and growth factors is not constitutive. In response to the ovarian steroid hormones, estrogen and progesterone, epithelial and stromal cells promote the synthesis of multiple growth factors and cytokines during the reproductive cycle and early pregnancy. Discussed below are some of these cytokines and growth factors that play critical roles in regulating uterine physiology. **Tables 1–3** show the list of growth factors and cytokines produced by the uterine cells during the reproductive cycle and early pregnancy, respectively.

Growth Factors

Insulin-Like Growth Factors (IGFs)

Among growth factors, insulin-like growth factors (IGFs) play a pivotal role in stimulating endometrial proliferation. Studies using mice lacking IGF1 revealed that in the absence of this growth factor, the uteri are hypotrophic. Further studies revealed a dramatic upregulation of IGF1 followed by phosphorylation of insulin-like growth factor 1 receptor (IGF1R) expressed in the uterine epithelium in response to treatment with estrogen. Activation of IGF1 signaling leads to nuclear accumulation of cyclin D1 and epithelial cell proliferation. Thus, IGFs mediate mitogenic action of estrogen in the uterus during the reproductive cycle (Nayak and Giudice, 2003).

During early pregnancy, *Igf1* mRNAs are observed in stromal cells of mouse uterus at days 4–6 of gestation. While the precise role of IGF1 during early pregnancy remains unclear, studies have shown that supplementation of the culture media with physiological concentration of IGF1 during IVF significantly increased blastocyst formation. Further, when extravillous trophoblast cells (EVT) were cultured in the presence of IGF1, it induced migration of EVT cells during the implantation process. Insulin-like growth factor binding proteins (IGFBPs) modulate the mitogenic and metabolic effects of IGFs, which play an important role in cell growth,

metabolism and embryonic development during early pregnancy (Singh et al., 2011). In mice, IGFBP-1 is detected in uterine epithelial cells and IGFBP-4 is the predominant IGFBP in stromal cells during the periimplantation phase. It has also been reported that IGFBP3 inhibits IGF1-induced DNA synthesis in the mouse endometrial stromal cells (Nayak and Giudice, 2003). IGFBPs including IGFBP1, IGFBP2, IGFBP3, and IGFBP4 are also expressed by human endometrial stromal cells upon differentiation (Giudice et al., 1993). As pregnancy progresses, IGFs and IGFBPs continue to play an important role in formation of the placenta. Inadequate production of IGFs or IGFBPs causes abnormal placentation (Davila et al., 2015; Nayak and Giudice, 2003).

Epidermal Growth Factor (EGF) Family

The EGF family of growth factors includes EGF, TGF- α , HB-EGF, amphiregulin, β -cellulin, epiregulin, and neuregulin. Many of these members are expressed in response to steroid hormones in rodent and human endometrium during the reproductive cycle and pregnancy. The EGF-like growth factors interact with receptor subtypes that belong to an ErbB gene family of tyrosine kinase receptors: *ErbB1* (EGFR), *ErbB2*, *ErbB3*, and *ErbB4*, which are known to be expressed in the uterine stromal cells. These receptors are structurally similar but differ in their ligand specificity and kinase activity. The expressions of EGF receptors are also regulated by steroid hormones. Studies have shown that during early pregnancy in mice, progesterone induces secretion of Indian hedgehog (IHH) by the uterine epithelial cells, which interact with their transmembrane Patched receptors (PTC) on the stromal cells to induce EGFR (Franco et al., 2010). Microarray analysis identified additional members of the EGF receptor family that are regulated by IHH, including *ErbB2/Her2*, *ErbB3/Her3*, and *ErbB4/Her4* (Franco et al., 2010). In vitro studies show that epithelial EGF via stromal EGFR induces stromal cell proliferation. Administration of steroid hormones, estrogen and progesterone, along with EGF, TGF- α increased the percentage of BrdU-labeled stromal cells. The stimulatory effect of EGF, TGF- α and steroid hormones on DNA replication in the uterine stromal cells was repressed by RG-13022, an inhibitor of the EGF receptor tyrosine kinase, suggesting that EGF–EGFR signaling is a critical driver of stromal cell

proliferation and differentiation. Consistent with these observations, it was found that mice lacking *Egfr* expression are severely subfertile. Pregnancy demise occurred shortly after embryo implantation due to defects in stromal cell proliferation and differentiation.

HB-EGF is a prominent growth factor of uterine receptivity to embryo implantation in both mice and humans. In mice, the soluble and the transmembrane form of HB-EGF are expressed exclusively at the implantation site prior to embryo attachment (Lim and Dey, 2009). Interestingly, the soluble form of HB-EGF increases the rate of human blastocyst hatching in vitro. Blastocysts from mice and human adhere to the epithelial cells expressing HB-EGF (Lim and Dey, 2009). Conditional ablation of HB-EGF expression in mouse uterine tissue markedly reduces the rate of implantation. Other growth factors including amphiregulin, beta-cellulin, epiregulin, neuregulin are expressed at the time of embryo implantation. However, due to their overlapping expression patterns around the implanting blastocyst at the time of attachment, mice with targeted disruptions of these growth factors do not exhibit implantation defects (Lim and Dey, 2009).

Fibroblast Growth Factors (FGFs)

Recent studies have shown that a subset of FGF family members including Fgf-1, -10, -18, and -21, are expressed by the stromal cells while the FGF receptors (FGFR) are expressed in the epithelium of rodent uteri (Li et al., 2011). Estrogen-mediated signaling by FGF–FGFR stimulates epithelial proliferation in the uterus. The FGFs via FGF receptors activate the extracellular-signal-regulated kinases 1 and 2 (ERK1/2) and/or PI3 kinase pathway to induce expression of cyclin D1. Cyclin D1 is required for progression of cell cycle during uterine epithelial proliferation. Progesterone mediated suppression of the FGFR–ERK1/2 pathway in uterine epithelia causes the epithelial cells to exit from the cell cycle and become “receptive” for embryo implantation (Li et al., 2011). Ablation of FGFR2 in the adult uterus render the female mice initially subfertile and later infertile with increasing parity (Filant et al., 2014).

Cytokines

Leukemia Inhibitory Factor (LIF)

Leukemia inhibitory factor (LIF) is a critical factor for embryo implantation (Stewart et al., 1992). It is a member of the IL-6 family and functions through the LIF receptor, which is associated with the signal transducer GP130. In rodent uterus, the expression of LIF is induced specifically in the glandular epithelium in response to a surge of estrogen immediately before implantation. Recent studies indicated that the conditional ablation of uterine epithelial estrogen receptor alpha in mice leads to a loss of LIF production by the glands, confirming the estrogen regulation of this factor (Kimber, 2005; Pawar et al., 2013). LIF regulates the remodeling of the uterine luminal epithelial cell–cell junctions at the site of implantation to facilitate embryo invasion. LIF secreted from the uterine glands binds to the LIF receptors on the luminal epithelial cells to activate STAT3 (signal transducer and activator of transcription 3). Epithelial STAT3, upon activation, suppresses the expression of the tight junction proteins (claudin-1, -2, -3), within the implantation window (Pawar et al., 2013). Additionally, LIF may be involved in the migration of uterine natural killer cells (uNK) during early pregnancy (Kimber, 2005).

In humans, LIF is expressed throughout the menstrual cycle with a striking increase in the mid- and late-secretory phase (days 18–28) and in early pregnancy. LIF is expressed primarily in the luminal and glandular epithelial cells. LIF-receptor mRNA is restricted to luminal epithelium throughout the cycle. LIF is detected in decidual leukocytes, which are abundant at the implantation site. Although the expression of *LIF* peaks at the time of implantation in humans, its role in this process is not clear. During mid-pregnancy, *LIF* and *LIF-receptor* have been detected in the decidua and chorionic villi of first trimester and term placenta (Kimber, 2005).

Interleukins

Interleukins are secretory cytokines, which are responsible for a variety of cellular functions. Although they are not direct targets of regulation by steroid hormones estrogen and progesterone, their actions are nevertheless important for endometrial functions in both mice and humans. Specifically, the expression of interleukin 11 (IL-11) rises transiently in the decidua upon embryo implantation, while that of its receptor, interleukin 11 receptor alpha (IL-11R α), is localized to this tissue. Consistent with this expression pattern, mice carrying a deletion of the gene encoding IL-11R α are infertile due to impaired decidual response. A recent study shows that inhibition of IL-11 function with an antagonist disrupts the proliferation and differentiation of stromal cells in pregnant mice and in human endometrial stromal cells (hESC) in vitro. In hESC, IL-11 and its receptor are believed to control mitotic expansion of hESCs obtained from early to mid-secretory stage endometrium (Dimitriadis et al., 2005).

Studies have shown that several interleukins such as IL-6, IL-9, IL-10, IL-11, IL-15, and IL-35 help create an immune-tolerant milieu that is essential for successful pregnancy. Many of these interleukins, (e.g., IL-6, IL-10, and IL-11) mediate cell–cell communication with the uterine stromal and embryonic cells via JAK-STAT pathways. IL-6-deficient mice exhibit reduced fertility and a decrease in viable implantation sites (Dimitriadis et al., 2005). During pregnancy, IL-10 is secreted by the uNK cells in the decidua as well as by the embryonic cells. It functions as an immune suppressive agent and a mediator of cross-talk between the fetal tissue and the uterus (Thaxton and Sharma, 2010). Studies in mice suggest that IL-11 signaling is required for decidual-specific maturation

of uNK cells. Interestingly, a recent study showed that IL-1 β , derived in part from infiltrating innate immune cells, affects stromal differentiation via effects on gap junction physiology in the human (Yu et al., 2017).

Transforming Growth Factor- β (TGF β)

Transforming growth factor beta (TGF β) 1–3 are founding members of the TGF β superfamily, which have profound effects on extracellular matrix (ECM) production, cell growth and differentiation. In the mouse uteri, individual TGF β isoforms are differentially expressed in epithelial and stromal cells during the reproductive cycle and early pregnancy. Similarly in the human endometrium, TGF β -1, -2, and -3 are expressed in both epithelial and stromal cells. Of the three, only TGF β -3 varies across the cycle, and, its expression increases in the glandular epithelium during the late secretory phase (Dimitriadis et al., 2005). The in vivo role of TGF β in the uterus remains elusive, partially because of the redundancy of the ligands and the lack of appropriate animal models as a result of the embryonic lethality in mice lacking TGF β ligands. In vitro treatment of preimplantation stage embryos with TGF β -1 increases total number of cells in expanded and hatching blastocysts. In addition, TGF β -1 increases the expression of oncofetal fibronectin, an anchoring trophoblast marker, indicating a potential role of TGF β in trophoblast adhesion during implantation. TGF β -1 also inhibits human trophoblast cell invasion by promoting the production of tissue inhibitor of metalloproteinases. Besides TGF β 1–3, several other TGF β superfamily ligands including bone morphogenetic proteins and nodal growth differentiation factor are also expressed in the uterus. Recent studies using tissue-specific knockout approaches have yielded new insights into this growth factor superfamily in uterine function and diseases (Li, 2014).

Colony Stimulating Factor (Csf) and Granulocyte-Macrophage Colony-Stimulating Factor (GM-CSF)

CSF via its receptor, c-fms, triggers JAK/STAT and/or PI3/AKT pathways to regulate cellular proliferation, differentiation and survival. It has been reported that in the human endometrium, estrogen upregulates CSF1 and GM-CSF during the proliferative phase and early secretory phase of the menstrual cycle. The uterine expression of these factors decline in the late secretory phase when progesterone begins to rise. In the human, CSF-1 protein is much higher in the pregnant than the non-pregnant uteri and is high in the placenta throughout gestation (Dimitriadis et al., 2005). CSF blocks the response of cytotoxic T lymphocyte precursors and protects the embryo against cytotoxic mechanisms.

In the mouse, there is a surge of GM-CSF following mating. This surge results in influx of leukocytes into the uterus. GM-CSF promotes cellular proliferation and differentiation that supports embryo growth including progression into the blastocyst stage and blastocyst hatching. It also regulates macrophage activity during pregnancy. GM-CSF null mice are not infertile. However, in the absence of uterine GM-CSF, there are abnormalities in the relative proportions of the different cell types contributing to the placenta resulting in gestational death of the fetuses (Dimitriadis et al., 2005).

Vascular Endothelial Growth Factor (VEGF)

VEGFs are a family of endothelial cell specific mitogens and are the main factors responsible for de novo blood vessel formation or vasculogenesis. The VEGF family consists of six members: VEGF-A, -B, -C, -D, -E and placental growth factor. These ligands bind to three cell surface receptors: VEGFR-1 (Flt-1), VEGFR-2 (Flk-1/KDR), and -3 that are type 3 receptor tyrosine kinases, all of which are expressed in the uterus. In both mice and humans, VEGF-A is the major angiogenic growth factor in the uterus. Although the expression of VEGF-A is regulated by both estrogen and progesterone in the uterus, decidual angiogenesis is mainly regulated by VEGF-A secreted from the progesterone receptor (PR)-expressing decidual cells (Kim et al., 2013). The highest level of VEGF-A expression is observed in the mid to late proliferative phase of the cycle.

In the mouse, the expressions of VEGF-A and VEGFR in the uterus dynamically change during estrus cycle and early pregnancy. During embryo implantation, VEGF-A regulates endometrial vascularization and vascular permeability, thereby rendering the endometrium “receptive” for embryo implantation. VEGF-A also regulates endothelial cell proliferation at implantation sites in rodents. Later in pregnancy, VEGF-A plays an important role in formation of the “vascular sinus folding” during placentation (Kim et al., 2013). Inadequate production of VEGF-A by the decidual cells causes abnormal placentation (Davila et al., 2015). A study using specific blockades of VEGFR indicated that VEGFR2 is critical for decidual angiogenesis, vascular remodeling, and pregnancy progression. While VEGFR1 signaling has no obvious effect, signaling via VEGFR3 moderately affects decidual angiogenesis (Douglas et al., 2009).

Uterine Pathologies Associated With the Dysregulation of Cytokines and Growth Factors

In response to steroid hormone signaling, growth factors and cytokines are expressed in different cellular compartment of the uterus. These factors then act in a paracrine fashion to regulate uterine physiology during the reproductive cycle as well as in pregnancy. Disruption of the endometrial stromal–epithelial crosstalk involving these cytokines and growth factors often results in altered uterine physiology leading to unsuccessful pregnancy outcomes. It has been shown that in pregnancies with intrauterine growth restriction, decreased expression of VEGFA and aberrant expression of angiopoietins are associated with angiogenic abnormalities during placentation (Kim et al., 2013). Studies have also shown that overproduction of VEGF receptor, sFLT1, in the placental trophoblast causes vascular dysfunction in preeclampsia and complications related to pregnancy (Fan et al., 2014).

Miscarriage remains one of the most prevalent obstetrical complications but little is known about the risk factors and etiology. Reduced expression of VEGFA has also been reported in endometrium of women with recurrent miscarriage. Elevated serum levels of certain cytokines such as IL-8 is associated with second-trimester miscarriages in women. Some cases of uterine pathology involving these cytokines, however, are much more complicated. It has been reported that elevated levels of IL-6 at the maternal–fetal interface are associated with fetal loss in mice. Similarly, increased levels of serum IL-6 was reported in women with first- or second-trimester miscarriage. However, another study showed reduced secretion of IL-6 in women with first-trimester miscarriage and altered decidual cell expression of IL-6 and its receptors in the placental bed of women with second-trimester miscarriage. Although a large number of cytokines are expressed in the uterus over the course of the reproductive cycle, functional redundancy among the cytokines makes dissecting the role of individual cytokines expressed in the uterus challenging (Lash and Ernerudh, 2015).

Aberrant growth factor signaling also adversely affects uterine physiology. As discussed earlier in this article, FGFs act in a paracrine manner via the FGF receptors to promote epithelial proliferation. Uncontrolled proliferation of the endometrial epithelium results in alterations of glandular architecture (shape and size) and an increase in endometrial gland-to-stroma ratio, leading to endometrial hyperplasia. Studies have shown that progesterone via its downstream target Hand- and neural crest derivatives-expressed protein 2 (HAND2) suppresses the production of several stromal FGFs curtailing epithelial proliferation (Jones et al., 2013; Li et al., 2011). It has also been reported that epigenetic silencing of *HAND2* is associated with endometrial hyperplasia and cancer (Jones et al., 2013), indicating that persistent activation of FGF signaling due to absence of *HAND2* affects normal uterine physiology.

Clinical Application

Assisted Reproductive Technology, IVF

Based on strong evidence from the animal and human data, GM-CSF became the first cytokine to be used in the human embryo cultures used for IVF procedures. Fluorescence in-situ hybridization analysis for 7 chromosomes (13, 16, 18, 21, 22, X and Y) was carried out in all blastomeres of embryos cultured until 8 cell stage with or without GM-CSF. Addition of GM-CSF at 2 ng/mL in the culture media resulted in 34.8% uniformly normal embryos, compared with 33.3% uniformly normal embryos in the absence of this cytokine (Agerholm et al., 2010). Today GM-CSF is widely used in the IVF clinics.

Although understanding the molecular biology of these cytokines has helped to advance the field of reproductive medicine, certain questions need to be addressed. For example, it is important to determine how the embryo's epigenome is influenced by manipulation of autocrine and exogenous cytokine signals. It is also important to determine whether maximizing autocrine signaling is sufficient to sustain optimal epigenetic parameters in IVF embryos.

Treatments of Uterine Pathologies

The majority of cases of endometrial hyperplasia are associated with compromised progesterone signaling that fails to inhibit epithelial proliferation. Understanding the growth factor signaling pathways that regulate uterine epithelial proliferation has helped to devise treatments for endometrial hyperplasia. Progesterone treatments have been successfully used to regress both simple and complex hyperplasia (Marra et al., 2014).

Glossary

5 α reductase type 1 An enzyme that catalyzes the reduction of the double bond between carbons 4 and 5 of many steroid substrates. In the cervix, 5 α reductase type 1 converts the steroid progesterone to 5 α progesterone, a less active steroid.

20 α -hydroxysteroid dehydrogenase An enzyme that catalyzes the conversion of progesterone into its inactive form, 20 α -hydroxyprogesterone.

Adherens junction A junction which joins the actin cytoskeleton to the plasma membrane to form adhesive contacts between cells or between cells and extracellular matrix.

Aquaporins Cell membrane proteins which selectively permit water to pass into and out of the cell.

Desmosomes Adhesive intercellular junctions that mechanically integrate adjacent cells by coupling adhesive interactions mediated by desmosomal cadherins to the intermediate filament cytoskeletal network.

Exocervix The portion of the uterine cervix extending into the vagina and lined with stratified squamous epithelium.

Ehlers–Danlos syndrome Group of inherited disorders that affect the connective tissues that support the skin, bones, blood vessels, and many other organs and tissues.

Endocervix The mucous membrane lining the canal of the cervix uteri.

External os The opening of the uterine cervix into the vagina.

Extracellular matrix (ECM) Complex network of non-cellular portion of a tissue composed of proteins and polysaccharides that are secreted locally by cells and remain closely associated with them to provide structural, adhesive and biochemical signaling support.

Fibrillar collagen Polymerized, supramolecular collagen organized in fibrils.

Glycosaminoglycans Long, linear, charged polysaccharides that comprise repeating pairs of sugars, of which one is an amino sugar.

Internal os The opening of the cervix into the body of the uterus.

Lysyl oxidase An enzyme that participates in the formation of collagen polymers by facilitating oxidative deamination of peptidyl lysine residues on collagen monomers, to form crosslinks between collagen tripeptides.

Marfan syndrome A connective tissue multisystemic disorder characterized by skeletal changes, cardiovascular defects, and ocular defects. It is an autosomal dominant inheritance, caused by a mutation in the fibrillin-1 gene.

Mullerian ducts Paired ducts of mesodermal origin in the embryo giving rise in the female to the fallopian tubes, uterus, cervix, and upper portion of the vagina.

Papanicolaou screening test (Pap) A method of cervical screening used to detect potentially pre-cancerous and cancerous processes in the cervix.

Parity Number of times a female has given birth to offspring.

Pericellular matrix Extracellular matrix located on the outer surface of a cell.

Portio supravaginalis The part of the cervix of the uterus lying above the attachment of the vagina.

Portio vaginalis The part of the cervix within the vagina.

Proteoglycans Glycoproteins that consist of a core protein with one or more glycosaminoglycan chains.

Spinnbarkeit The elastic quality that is characteristic of mucus.

Tight junctions Type of cell-cell junction found in epithelia that forms a barrier that is impermeable to most soluble molecules in the space between adjacent epithelium. Major components of tight junctions are claudin and occludin proteins.

Anatomy

The cervix is a part of the female reproductive tract which connects the uterus with the vagina. The cervix is in the pelvic cavity, anterior to the rectum and posterior to the bladder and is supported by uterosacral and lateral ligaments. It receives its blood supply from branches of the uterine artery and vaginal arteries of the internal iliac arteries (Nott et al., 2016). The cervix is developed along with the uterus and vagina from Mullerian ducts (paramesonephric ducts) (Spencer et al., 2005). Fusion of the two Mullerian ducts vary between species resulting in species specific gross anatomy of the uterus and cervix. For example, humans have a single cervix and single uterine cavity; mice and cows have a single cervix that extends into two uterine horns while rabbits have two distinct cervixes each of which extends into a separate uterine horn (Fig. 1). While contiguous with both uterus and vagina, the cellular/

Fig. 1 Diagrammatic representation of species-specific variations in cervix and uterine architecture. (A) Single cervix opens into a single uterine cavity (e.g. women). (B) Single cervix opens into a bicornuate uterus (e.g. cow). (C) Two distinct cervical canals each of which separately extend into a uterine cavity (e.g. rabbits). The figure is adapted with permission from [Vodopich and Moore, 2001](#), © 2001 McGraw-Hill.

extracellular composition and functions are distinct from these compartments and vary between the non-pregnant and pregnant state. Consistent with its autonomy, cervical pathophysiology is an independent risk factor in the complications associated with pregnancy and birth ([Gee, 2009](#)).

There is great variation among species in length and diameter of the cervix, in the point of transition from columnar to squamous epithelia, the presence of epithelial glands and in the architecture of the epithelial mucosal folds. In humans, the cervix is small before puberty and increases in size with onset of puberty along with maturation of the epithelia and formation of glands ([Hafez, 1973](#)). In the non-pregnant adult woman, the dimensions of the cervix are 3 cm in length and 2 cm in diameter, though it can vary depending on age, parity and stage of menstrual cycle ([Nott et al., 2016](#); [Singer and Jordan, 2009](#)). Structurally, the cervix is divided into the upper portion, supravaginal portion (*portio supravaginalis*) and a lower portion (*portio vaginalis*). The central canal which connects the uterine cavity with the vaginal cavity is the inner cervical canal. This canal is lined by an epithelium and is termed the endocervix. The opening of the cervical canal at the uterine end is called the internal os and the opening at the vaginal end is called the external os ([Singer and Jordan, 2009](#)). The outer portion of the cervix extends into the vagina and is termed the ectocervix or exocervix. The parts of the cervix are depicted in [Fig. 2](#). Epithelial glands are present in the human but absent in mice. With respect to mucosal folds present in the endocervix, humans have branching folds on the surface, cows have four longitudinal annular rings arranged spirally, horses have no annular rings and pigs have corkscrew shaped projections ([Hafez, 1973](#)).

Fig. 2 Histology of the mouse and human cervix. (A) Longitudinal mouse cervical section stained with Hematoxylin and Eosin. The external os, endocervical canal, simple columnar uterine epithelium, squamocolumnar junction and squamous epithelium are indicated. (B) Human cervical tissue section stained with Hematoxylin and Eosin. Note that the human endocervix is lined with simple columnar epithelium and studded with cervical glands. The squamocolumnar junction (transformation zone) is distinct in human cervix. The exocervix is lined with stratified squamous epithelium. Image credit: Human Protein Atlas. Functions

Non-pregnant state	1. Regulates motility of the sperms into the uterus 2. Allows outward flow of menstrual blood from the uterus into the vagina 3. Provides immune and barrier function of the reproductive tract
Pregnancy	1. Maintains pregnancy by withstanding the pressure generated by the growing fetus(es) and uterus 2. Provides immune and barrier function to protect the uterine compartment and fetus against environmental insults such as ascending infection
Parturition	Dilates sufficiently to facilitate birth process
Postpartum	Repositions and repairs itself to protect upper reproductive tract from external insults to ensure successive pregnancies. Regains structural integrity and mechanical strength.

Histology

Similar to any typical tubular organ, the cervix has stroma and epithelial compartments. During development, the Mullerian ductal epithelium proliferates antero-posteriorly to make two distinct epithelial cell types along the female reproductive tract. The uterus and upper portion of the cervix are lined with simple columnar epithelium and lower portion of the cervix and vagina are lined with stratified squamous epithelium. Hence, the cervix is comprised of two types of mucosal epithelium. The transition between these two cell types termed the squamocolumnar junction varies between species and stage of the cycle. In women, the endocervix and cervical glands are lined with simple columnar mucus secreting epithelium. In contrast, the ectocervix is lined with stratified squamous epithelium. In mice, only the uppermost portion of the endocervix harbors columnar epithelium while much of the endocervix and the ectocervix is comprised of squamocolumnar epithelium (Fig. 2). The proliferation and secretory behavior of the epithelium is highly variable depending on the stage of the cycle and pregnancy status (Singer and Jordan, 2009). The stromal compartment consists of multiple cell types and extracellular matrix (ECM). The cell types include fibroblasts, smooth muscle cells, and immune cells. The extracellular matrix is composed of fibrillar collagen, elastic fibers, glycosaminoglycans, proteoglycans and matricellular proteins. Both the epithelial and stromal compartments undergo structural changes depending on the stage of the cycle or pregnancy status (Timmons et al., 2010).

Epithelium

In Non-pregnancy

The cervical epithelium functions to provide a structural and an immunoprotective barrier as well as produce a cycle specific mucosal composition to regulate fertility. The epithelium produces junctional barrier proteins, cytokines, chemokines, antimicrobials, pattern recognition receptors and protease inhibitors to achieve these functions. Epithelial cell proliferation and the properties of their mucosal secretions undergoes significant changes during the menstrual cycle. These properties of mucus influence sperm motility and survival within the female reproductive tract thus influencing overall fertility (Martyn et al., 2014). The mucus is mostly composed of water, mucins, ions, antimicrobials and various other factors. Mucins are large glycosylated polymers that alter visco-elastic properties of the cervical mucus. Five different mucin proteins are known to be secreted by the cervical epithelia (Martyn et al., 2014). At the time of ovulation, the cervical mucus has low viscosity with marked spinnbarkeit and a high ionic concentration capable of forming a clear fern pattern. During this time, mucin polymers are arranged in such a way to permit sperm movement. The mucus turns highly viscous with low spinnbarkeit and exhibits no fern pattern at other stages of cycle to prevent sperm entry (Jequier, 2009) (Fig. 3). The functions of the cervical epithelia and its mucus are well conserved between species including human and mice.

In Pregnancy

The cervical epithelium serves as a physical barrier of protection, provides immune surveillance and modulates the local tissue steroid environment to maintain pregnancy or initiate cervical ripening for parturition (Timmons et al., 2010). Through pregnancy, the epithelium undergoes extensive proliferation followed by differentiation (Fig. 4). In the latter part of pregnancy, the upper layers of terminally differentiated epithelia are laden with mucin – secreting vacuoles. In mice, the thickness of this mucosal epithelium reaches a maximum at the time of birth on day 19 of gestation and regresses during the postpartum period. Mucus provides a physical and immune- barrier, while epithelial cell junctions such as tight junctions, adherens junctions and desmosomes are formed between adjacent cells in the pericellular space and serve to regulate the movement of molecules between cells (Timmons et al., 2010). Further, the barrier function of epithelium is complemented by the structure of the pericellular matrix and its constituents. In addition, the cervical epithelia play a role in tissue hydration through the expression of aquaporins. Similar to non-pregnancy, the epithelium at pregnancy also produces cytokines, chemokines, antimicrobials, pattern recognition receptors and proteases inhibitors to achieve its functions. While the cervical epithelia and the mucus it secretes have a similar function in most species,

Fig. 3 Steroid hormones regulate the physical properties of cervical mucus to control sperm entry. During ovulation, an estrogen dominant phase, cervical mucus has a low viscosity with spinnbarkeit and mucin polymers (shown in yellow) are arranged in such a way to permit sperm movement into the upper reproductive tract. In contrast, the cervical mucus in progesterone dominant phases is highly viscous with low spinnbarkeit and mucin polymers form a barrier to prevent sperm entry.

primates including humans are unique in that during pregnancy, the cervical glands and epithelium secrete a thick mucus which fills the endocervical canal to form a plug. The cervical mucus plug is present till term and will be shed only around the time of parturition. Its unique composition provides physical as well as immunological barrier function (Becher et al., 2009).

Stromal Compartment

The stromal compartment is composed of fibroblasts, smooth muscle cells and a rich and complex ECM. The composition and structure of the ECM determines mechanical rigidity (Fig. 4). While not a highly-vascularized tissue, there are blood vessels in the stroma and cycle-specific changes in vascularity. The endocervix has numerous sensory nerve endings while the ectocervix has only few. In addition, the stroma is populated by innate and adaptive immune cells that are poised to respond to danger signals from the cervical epithelia or pathogens. The stromal compartment undergoes modest changes in hydration, vascularity and immune cell abundance and function in the non-pregnant state. During pregnancy, the stromal cell populations proliferate with increased tissue vascularity and hydration at term. Resident immune cells display an immunosuppressive phenotype during pregnancy. An influx of tissue monocytes just prior to birth and expression of markers of proinflammatory and immunotolerance/repair macrophages after birth suggest an important role of immune cells in postpartum repair of the cervix.

Remodeling of the Cervical Stroma in Pregnancy

From early pregnancy to the onset of labor, the cervix is transformed from a closed and rigid to a soft and compliant structure that opens sufficiently for fetal exit from the birth canal. Concurrent with the dynamic changes required to facilitate cervical compliance, the cervix must maintain its structural and mechanical integrity to protect the pregnancy until term. This dynamic process termed cervical remodeling can be divided into four overlapping phases termed softening, ripening, dilation, and postpartum repair (Word et al., 2007). In each phase, specific alterations in the synthesis, processing, and assembly of ECM components collectively orchestrate the gradual structural reorganization of the ECM that allows for the decline in mechanical strength of the cervix (Fig. 4). Key features that define each phase are well characterized in the mouse (Mahendroo, 2012). During softening, there is a gradual decline in stiffness of the cervix as compared to the non-pregnant cervix. It is a slow and incremental process and continues until late pregnancy. This softening process coincides with the period of uterine quiescence. In contrast to softening, the ripening phase is a rapid process and happens one day before delivery in the mouse. With onset of uterine contractions, the cervical canal undergoes dilation thus expanding to a maximal size to facilitate the delivery process. After birth, a remodeling process is initiated to allow recovery of the cervix back to the non-pregnant rigid and closed state to protect the reproductive tract from environmental insults.

Terminology used to assess cervical changes in pregnant women include softening, shortening, funnelling, effacement and dilation (Cunningham et al., 2013b; Myers et al., 2015). Softening can be assessed by digital exam while vaginal ultrasound allows visualization of cervical length from the internal to the external os (i.e. shortening) and the funnel shape the cervix assumes with progression of effacement and dilation. As the frequency, intensity, and duration of uterine contractions increases, the cervix becomes thinner by shortening the cervical canal in a process called effacement and dilatation. This coincides with the descending fetal head into the birth canal.

Fig. 4 Summary of the dynamic change in steroid hormones, tissue stiffness, ECM organization and immune cell populations that characterize the non-pregnant (NP), pregnant and postpartum (PP) cervix in mice. As depicted in the graph, the concentration of progesterone, estrogen and relaxin varies over the 19 day pregnancy in mice and is distinct during each phase of cervical remodeling. Cervical stiffness gradually declines during the softening phase of remodeling and reaches a maximal low at birth. The change in the mechanical properties of the cervix is determined in part by alterations in levels and ratios of progesterone, estrogen and relaxin. Lower panel: Schematic depicting changes in the cervical epithelium (shown in yellow) and the stroma on pregnancy days 12 and 18 and postpartum relative to the NP cervix. During pregnancy, the epithelium (shown in yellow) undergoes extensive proliferation and differentiation. Compared to NP, the number of epithelial layers is increased during pregnancy and the terminally differentiated epithelial layers (indicated in the darker yellow) are laden with mucus filled vacuoles that secrete mucus to provide physical as well as immunological protection. Hyaluronic acid synthesis along with junctional proteins in the late pregnancy epithelia are critical to maintain cervical barrier protection. Within the stroma region, collagen and elastic fibers undergo a dramatic reorganization during pregnancy. In the NP cervix, collagen and elastic fibers appear densely packed, linear and form parallel bundles. During pregnancy, the elastic fibers lose their branching pattern and collagen fibers have a reduced number of strength bearing crosslinks. Under the control of progesterone and estrogen, the synthesis, processing and assembly of collagen and elastic fibers is altered to allow the progressive decline in tissue stiffness required for cervical opening during birth. In addition, changes in the composition of the ECM during pregnancy (e.g. a decline in thrombospondin 1 and 2 (THBS 1 & 2) and increase in hyaluronic acid) also contribute to increased tissue compliance. Relative to the NP cervix, resident immune cells (not shown) are quiescent during pregnancy. In preparation for postpartum repair, monocytes and eosinophils infiltrate the cervix before parturition while neutrophils and macrophages (M1, proinflammatory macrophages; M2, tissue repair macrophages) are increased at birth. These immune cells function to clean up the disorganized ECM. During the PP repair phase the organization and structure of collagen and elastic fibers is recovered back to the NP state.

ECM remodeling

The fibrillar collagens, collagen I and III, are the predominant structural proteins in the cervix and significantly influence mechanical properties of the cervix (Mahendroo, 2012). The content of collagen does not change in the cervix presumably due to its coordinated regulation of synthesis and degradation. However, the synthesis and assembly of collagen fibers are modified early in pregnancy (softening) with reduced expression and activity of the enzyme lysyl oxidase (Nallasamy and Mahendroo, 2017). This enzyme forms cross-links on collagen and elastic fibers and the degree of cross-links correlates directly with mechanical strength and structure. Specifically, reduction in cross-link density of newly synthesized collagen in early pregnancy in parallel with collagen turnover is believed to alter tissue tensile properties to allow for the progressive increase in compliance in late pregnancy. In addition to modifications in processing of collagen fibers, reduction in the expression of matricellular proteins such as thrombospondin 1 and 2 (THBS 1 & 2) also influence collagen structure (Fig. 4). Elastic fibers also contribute to the cervical mechanical properties. They are predominantly localized in the subepithelial stromal region surrounding the endocervix and undergo remodeling during pregnancy (Nallasamy et al., 2017). Synthesis of the glycosaminoglycan, hyaluronan is elevated during cervical ripening in women, mice, rabbit and numerous other species. Hyaluronan is a hydrophilic molecule with proposed function in the ECM of the cervical stroma as well as in maintenance of barrier function of the cervical epithelia to protect against infection (Akgul et al., 2014).

Hormonal Regulation of Cervical Function

The functions of the non-pregnant and pregnant cervix are in part regulated by steroid hormones (e.g. estrogen, progesterone), and peptide hormones (e.g. relaxin) (Cunningham et al., 2013b; Mahendroo, 2012; Nallasamy et al., 2017; Sherwood, 2004). In most species estrogen and progesterone are synthesized in other tissues and enter the cervix to act through their receptors, estrogen receptor α and progesterone receptor respectively. These receptors are expressed in both epithelial and stromal cells. The fluctuation in the levels or ratio of estrogen and progesterone results in a change in the function of the cervical epithelium and stroma. For example, in the non-pregnant cervix, high levels of estrogen around the time of ovulation stimulate the secretion of cervical mucus suitable for sperm movement (Fig. 3). In contrast, high levels of progesterone produce mucus incompatible for sperm motility.

Within the cervical microenvironment during pregnancy, steroid hormone levels can be further regulated by the expression of enzymes that inactivate steroids (for example progesterone can be metabolized by steroid 5 α reductase type 1 and steroid 20 α hydroxysteroid dehydrogenase in the mice and 17 β -hydroxysteroid dehydrogenase type 2 in the human (Cunningham et al., 2013b)). In addition, relaxin synthesized in the ovary can act through its receptor, Rxfp1 to facilitate epithelial cell proliferation and ECM remodeling during cervical ripening (Sherwood, 2004). During pregnancy, elevations in the progesterone/estrogen ratio regulate epithelial cell proliferation, differentiation, mucosal layer formation and cervical mucus plug secretion. Concurrently, these hormones regulate the synthesis, processing, and assembly of stromal extracellular matrix constituents. These carefully timed molecular changes prepare the cervix for birth by gradually increasing the compliance of the cervix during the softening phase. Around the time of parturition, decline in the progesterone to estrogen ratio triggers a cascade of events to achieve cervical ripening and dilation and subsequently parturition.

Clinical Significance

Induction of Cervical Ripening for Labor

In some women, cervical ripening and onset of uterine contractions are not initiated by 40 weeks of gestation. In these cases, labor must be induced first by exogenous administration of prostaglandins to induce cervical ripening followed by oxytocin to induce uterine contractions and subsequently vaginal delivery. Prostaglandins are a group of compounds that induce cervical ripening presumably by increasing the activity of proteases that degrade the ECM to facilitate cervical ripening and dilation. While prostaglandins are sufficient to induce cervical ripening in women and animal models, studies in mice suggest they are not an essential mediator of cervical ripening in normal gestation (Timmons et al., 2014). They are key mediators of cervical ripening induced by infection. In addition to pharmacologic methods, induction of cervical ripening can be done using mechanical techniques. These include transcervical placement of a Foley catheter with or without extra amniotic saline infusion, hygroscopic cervical dilators, and membrane stripping (Cunningham et al., 2013a).

Cervix and Premature Birth

Premature birth, defined as birth less than 37 of a 40-week gestation, can be induced by numerous etiologies. Irrespective of cause, premature cervical remodeling is a common endpoint that usually precedes preterm labor (Romero et al., 2014; Vink and Feltoich, 2016). While the underlying cause for premature birth is unidentified in roughly 50% of premature births, known risk factors include infection, premature rupture of membranes, lifestyle factors (diet, stress, obesity, age, smoking), multiple fetuses and a previous preterm birth. In some cases of preterm birth, cervical dysfunction is the initiating cause of preterm birth. For example, preterm birth can result from cervical insufficiency, defined as premature cervical opening in the absence of any uterine contractions

Fig. 5 Transvaginal ultrasonographic measurement of cervical length in women. (A) This image shows the length (*dotted yellow line*) and appearance of a normal cervix at 29 weeks of gestation. (B) This image of a cervix taken from a woman at 23 weeks of gestation shows funneling at the internal os and a prematurely reduced cervical length (*dotted yellow line*). This is an indicator of potential preterm birth risk. Photograph courtesy of Dr. Jodi Dashe, University of Texas Southwestern Medical Center, Dallas, TX.

and is due to structural defects in the cervical ECM. It is believed to be caused by acquired (e.g. surgery, injury) or intrinsic genetic defects in collagen and elastic fiber assembly (e.g. Ehlers–Danlos syndrome and Marfan syndrome) (Anum et al., 2009; Vink and Feltovich, 2016). In addition, premature cervical shortening as determined by vaginal ultrasound is a risk factor for premature birth (Fig. 5). A length less than 25 mm in women with a prior sPTB or less than 20 mm in unselected women based on the transvaginal ultrasound measurement is considered as a short cervix and currently is the best clinical indicator of premature cervical remodeling (Fig. 5) (Iams et al., 1996; Vink and Feltovich, 2016).

Human Papilloma Virus and Cervical Cancer

Cervical cancer is the most common gynecologic cancer in women. Most cervical cancers result from human papillomavirus (HPV) infection. HPV infection is a sexually transmitted infection. Chronic infection results in gradual transformation of cervical epithelia to precancerous lesions which eventually will form a cancer. The Papanicolaou screening test (Pap) provides accurate screening for neoplasia. Vaccination against the subtypes HPV-16 and HPV-18 reduces the incidence and persistence of infections and the incidence of HPV-mediated neoplasia (Hoffman et al., 2016).

Conclusion

The cervix plays a distinct and critical role in the non-pregnant and pregnant female to regulate fertility, maintain pregnancy and ensure safe delivery of a term fetus during parturition. The steroid hormones estrogen and progesterone are key mediators of the dynamic changes in the cervix. The peptide hormone relaxin also plays a role in cervical ripening in late pregnancy. During pregnancy, the uterine cervix undergoes an ECM reorganization of impressive scope and magnitude to transition the cervix from closed and rigid to one that is flexible to allow delivery of a term infant. Understanding this fascinating biological process will aid in prevention of premature birth, a leading cause of infant death globally.

Structure and Function

The cervix is the muscular canal at the tapering end of the uterus. It can be divided into two histologically distinctive regions, endocervix and ectocervix/exocervix (**Fig.1**). The endocervix communicates with the uterine cavity via the internal orifice of the uterus (internal os), and the ectocervix opens into the upper vagina via the external orifice of the uterus (external os).

Endocervix

The endocervix is the upper proportion of cervix that is lined by a single folded layer of mucus-secreting columnar epithelium (**Fig.2**). The mucinous epithelium invaginates into the substance of the cervical stroma, forming the endocervical glands. These cervical glands secrete cervical mucus, a viscous fluid containing glycoproteins.

Cervical mucus

Cervical mucus is a hydrogel consisting of 90–95% water and a heterogeneous mixture of mucin glycoproteins. The physical properties and the biochemical composition of cervical mucus change during the menstrual cycle. When the ovulation approaches, cervical mucus becomes thinner and more watery and is so-called “egg white cervical mucus”, as it resembles raw egg white. Egg white cervical mucus is believed to be preferable mucus for conception, as it provides an easy pathway for the sperm to swim through.

The cervical mucus layer on the surface of the cervix works as barrier to prevent infection. Cell-surface (MUC1, MUC4 and MUC16) and gel-forming (MUC5B, MUC5AC, MUC6) mucins produced by endocervical epithelium contribute to the formation

Fig. 1 Structure of Uterine Cervix.

Fig. 2 Squamocolumnar Junction in Human Cervix. KRT14 and TP63 immunohistochemistry stained stratified squamous ectocervical epithelium. SCJ is indicated by an arrow.

of the mucus layer in the cervical canal (Andersch-Bjorkman et al., 2007). In addition, the quality of cervical mucus significantly influences the fertility, as interactions with cervical mucus affect the penetration of spermatozoa into the uterine cavity (Martyn et al., 2014). Cervical mucus also works as lubricant during sexual intercourse.

Ectocervix (Exocervix, Portio Vaginalis)

The ectocervix is the supravaginal portion of the cervix, which is lined by stratified squamous epithelium continuous with vaginal epithelium. In the multi-layered epithelium of ectocervix and vagina, new cells are formed in the most basal layers by mitotic division, and the daughter cells move upwards, gradually changing the morphology from a cuboidal to a more flattened shape. The formation, maturation and loss of cells occur continuously under the influence of systemic ovarian hormone levels. The stratified squamous epithelium of vagina and ectocervix is an important battlefield in defense against pathogenic infections. The most apical layers of the ectocervical epithelium are permeable to immunoglobulins due to absence of classical cell-cell adhesions. Instead, cells in the suprabasal and basal epithelial layers form an exclusionary barrier with high densities of tight junctions, adherens junctions and desmosomes (Blaskewicz et al., 2011). Hence, in ectocervical epithelium the mechanical barrier of basal/suprabasal layers in combination with the permeable apical layers containing large-molecule immunomediators constitutes the first line of defense against sexually-transmitted infections for the entire female reproductive system.

Squamocolumnar Junction (SCJ)

Simple columnar epithelium of endocervix and stratified squamous epithelium of ectocervix meet within the cervical canal. The boundary is called the squamocolumnar junction (SCJ) (Fig. 1). The boundary can be highlighted by markers for columnar and squamous epithelial cells. For example, cytokeratin 14/KRT14, a marker for squamous epithelium, is expressed in ectocervical epithelium but not in the mucinous epithelium of endocervix (Fig. 2A and B). In mice and rats, SCJ is located at the boundary between simple columnar uterine epithelium and stratified squamous ectocervical epithelium as these species lack an endocervix with mucinous glands.

Formation of SCJ

During development, the Müllerian ducts (MDs) undergo a dynamic transformation from simple tubes consisting of homogeneous epithelium and mesenchyme into distinct organs, namely the oviduct, uterus, cervix and vagina (Kurita, 2010). There is no epithelial boundary in the MD. The uniform MD epithelium (MDE) then differentiates into diverse cell types with unique functions in each organ. The key role of mesenchyme in the cell fate specification of MD derived organs was first demonstrated by Cunha in a classic tissue recombination study (Cunha, 1976). In the experiment, epithelial (E) and mesenchymal (M) tissues from the uterus (Ut) and ectocervix/vagina (Vg) of newborn mice were recombined, grown in adult female syngeneic mice as kidney transplants, and the epithelial morphology was analyzed one month later (Fig. 3). A series of studies utilizing this technique established that the organ-specific epithelial cell fate of the uterus and ectocervix/vagina is dictated by the underlying mesenchyme. This epithelial specification occurs within a specific developmental time window. Accordingly, the original position of the SCJ is determined by the differences in the inductive activity of underlying mesenchymal cells of endocervix and ectocervix.

Molecular mechanism of ectocervical differentiation

In the lower MD, the expression of Δ Np63, a N-terminal truncated isoform of p63 transcription factor (TP63, Fig. 2C), determines the cell fate of MDE to become squamous ectocervical/vaginal epithelium or columnar endocervical/uterine epithelium. The mesenchyme of ectocervix and vagina induces the expression of Δ Np63 in MDE by secreting paracrine factors, namely bone morphogenetic protein 4 (BMP4), activin A, fibroblast growth factor 7 (FGF7) and FGF10 (Terakawa et al., 2016) (Fig. 4). In MDE, FGF signaling is transduced by FGFR2IIIb/MAPK/ERK pathway, and BMP4 signaling is transduced by the canonical SMAD pathway. Activin A signaling is mediated by the expression of runt related transcription factor 1 (RUNX1), but molecular mechanism underlying induction of RUNX1 by activin A is unclear. While FGF, BMP and activin signaling pathways are essential for the activation of Δ Np63 in MDE, maintenance of Δ Np63 expression in ectocervical epithelium is independent of all three mesenchymal factors. Thus, the SCJ is maintained in the cervical epithelium independent of external signals.

Changes in the SCJ

In infancy and childhood, the SCJ locates at its original position, just above the external os, but it moves as influenced by hormones when ovaries become active. Ectropion or ectopy of endocervix is defined as the presence of endocervical epithelium on the ectocervix, below the external os. Endocervical ectropion is a physiological condition common for women of reproductive age. The degree of ectopy changes over the time and varies by individual. In some extreme cases, the columnar epithelium extends into the vaginal fornix. During menopause, the process of ectropion reverses, and the SCJ inverts to lie above the external os.

Transformation zone

The term "transformation zone" is sometimes used interchangeably with the SCJ, but it often refers to the wider area within which the SCJ moves. The SCJ is more specific to the boundary of epithelium, whereas the transformation zone includes underlying stroma as well. The transformation zone is clinically important because ~95% of cervical squamous cell carcinoma occur in this region.

Fig. 3 Scheme of Tissue Recombination Experiment.

Fig. 4 Formation of SCJ in developing cervix.

Metaplastic Change

Endocervical squamous metaplasia

Squamous metaplasia of endocervix is defined by a presence of islands of squamous cells above the SCJ. It is a common physiological condition believed to be associated with the hormonal changes that occur during puberty in young girls. Although squamous metaplasia is often described as the transformation of columnar endocervical epithelium to squamous ectocervical-like epithelium, there is no experimental evidence for the conversion of epithelial cell type in the pathogenesis of endocervical squamous metaplasia. There is no risk of malignant transformation for squamous metaplasia. Nevertheless, the metaplastic change within the endocervix may increase the risk for human papilloma virus infection (Hwang et al., 2012), which is a risk factor for cervical cancer.

Ectocervical/vaginal adenosis

Ectocervical adenosis is a benign epithelial lesion defined as development of glandular (columnar) epithelium within the stratified squamous epithelium of the ectocervix (below the SCJ). Ectocervical adenosis often occurs in young women, but it usually disappears by menopause as squamous epithelium replaces adenotic cells. Since it is mostly asymptomatic, the accurate prevalence is unknown. There are three major epithelial histopathologies, endocervical, endometrial and tubal types. The condition is considered congenital, as it has been observed in fetuses and infants. Studies with genetically engineered mouse models demonstrated that ectocervical/vaginal adenosis occurs due to faulty epithelial cell fate decision, supporting the congenital nature of this condition. Its pathogenesis usually involves exposure to diethylstilbestrol or other estrogens (Laronda et al., 2012). However, idiopathic cases in women who had no history of in utero hormone exposure have also been reported. The incidence of ectocervical/vaginal adenosis in women who were exposed to diethylstilbestrol in utero (DES daughters) significantly varies between reports utilizing different detection methods (e.g. colposcopy versus histopathology). For instance, routine cytology screening detected vaginal adenosis in only a quarter of patients in which biopsy histology identified the presence of a lesion (Robboy et al., 1976). Some suspect de novo formation of adenosis in ectocervix and vagina of adult women. However, given the low detection sensitivity of routine colposcopy and cytology screenings for adenosis, the adenosis cases that appear to be de novo are likely due to an increased visibility of originally hidden small adenosis lesions by a reactive change to hormone treatments. There is no experimental data directly indicating if and how adenosis transforms to adenocarcinoma. The risk of adenocarcinoma is extremely small in women who have adenosis but no history of diethylstilbestrol exposure. Nevertheless, some doctors recommend careful screening and follow-up for women with adenosis.

Cervical Wall

The cervical wall consists of subepithelial fibrous stroma and smooth muscle. The concentration of smooth muscle cells in cervical stroma diminishes from the upper towards the lower part, where smooth muscle cells are scattered, forming very few bundles. Based on the morphology and distribution, it has been long believed that the cervical smooth muscle is non-functioning. However, a recent study demonstrated that the stromal wall around the internal os contains 50–60% smooth muscle cells that are circumferentially organized in the periphery of the cervical wall, suggesting that smooth muscle cells contribute to the tensile strength and firmness in the upper portion of the cervix (Vink et al., 2016). In contrast, the lower cervix around the external os contains only ~10% of smooth muscle cells randomly scattered in the stroma. Thus, the firmness of the lower cervix is primarily due to the rigid extracellular matrix (ECM) that is rich in collagen and elastic fibers. Fibrillar type I and III collagens are the major constituents of the ECM in cervix. Particularly, Type I collagen is the most abundant protein in cervical stroma. The circumferentially arranged collagen fibers give the cervix mechanical strength to withstand forces encountered in pregnancy. The cervical stroma undergoes dynamic remodeling involving rearrangement of collagen fibers during pregnancy.

Hormone action

The function of hormones in the human cervix is primarily assessed by the correlation between hormone levels and cervical functions. However, such approach does not distinguish the direct and indirect actions of different hormones that are present in the system at the time of analysis. Since manipulation of systemic hormone levels beyond the administration of hormone-containing medications is unethical, our knowledge of hormone actions on the cervix is mostly derived from studies with animal models. Particularly, genetically engineered mouse models have contributed significantly to our understanding. It should be noted that the hormone actions in model animals may not be identical to those in women, given the fundamental difference in the duration of reproductive cycle and gestation as well as anatomy of the cervix.

Hormone Actions on Endocervix

In pregnant women, endocervical glands increase in mass as endocervical epithelial cells proliferate. While the observation indicates the growth of endocervical epithelium is under the control of systemic hormones, the hormones that drive the proliferation of endocervical epithelial cells has not been determined. The absence of equivalent tissues between rodents and humans is one of many factors that impede the mechanistic studies of hormonal control on endocervical function. Cellular and biochemical changes in human endocervix during the menstrual cycle remain undetermined.

Hormone Actions on Ectocervix

In human ectocervix, the epithelial proliferation rate is highest in the parabasal layer. The proliferation rate peaks at luteal phase in menstrual cycle and during pregnancy (Konishi et al., 1991), suggesting the proliferation of ectocervical epithelium is stimulated by 17 β -estradiol and progesterone. In human and mouse ectocervices, the receptors for estrogen (ESR1) and progestin (PGR) are expressed in both epithelial and stromal cells. Mouse genetic studies demonstrated that the proliferation of stratified squamous epithelium in the cervix and vagina is regulated by estrogen through ESR1 in stromal cells (Buchanan et al., 1998). In contrast, progesterone stimulates proliferation of ectocervical epithelium through the epithelial PGR (Mehta et al., 2016). Since epithelial

ESR1 is required for the expression of PGR in the epithelium, ESR1 in both epithelial and stromal cells is required for the full growth response of ectocervical epithelium to estrogen and progestin. Similarly, differentiation and apoptosis of ectocervical/vaginal epithelial cells are regulated by estrogen and progestin through ESR1 and PGR in both epithelial and stromal cells.

Pregnancy Associated Changes

The cervix must undergo a dramatic process of remodeling to allow for passage of the fetus (Timmons et al., 2010). Three phases of prepartum cervical remodeling have been proposed (Word et al., 2007), softening, ripening and dilation. In this section, the molecular aspects of softening and ripening of cervix is described.

Softening

The initial softening phase is a slow, progressive process for reorganization of ECM. In women, the cervix begins to soften as early as 1 month of gestation. Softening of the cervix is characterized with a progressive increased turnover of the ECM including the dispersion and rearrangement of the collagen fibrillar network. At the same time, vascularity increases and leukocytes are recruited to the subepithelial stroma in this phase.

Ripening

Ripening of cervix is the phase of accelerated softening and begins prior to the onset of labor contractions and cervical dilation. In this phase, firmness of cervical ECM is reduced further by a decrease in collagen fiber alignment, degradation of collagen cross-linking and increase in water intercalate among the collagen fibers. These changes are considered as a part of inflammatory reactions, which are characterized as the increase in pro-inflammatory cytokines (e.g. interleukin-8, interleukin-6 and granulocyte colony-stimulating factor) and the influx of granulocytes, such as neutrophils and eosinophils. In addition, macrophages increase in cervical epithelium and stroma at labor. During the process of ripening, the cervix loses gross morphological characteristics such as endocervical glands and smooth muscles. How this morphological transformation occurs during ripening of cervix is not well understood.

Progesterone

The molecular mechanism that regulates the transition from softening to ripening in normal pregnancy is not fully elucidated. The reduced progesterone signal has been implicated in the initiation of the cervical ripening process, based on the decline of systemic progesterone prior to the onset of labor in many species, including rodents and some primates. However, some aspects of cervical ripening in women occur when progesterone concentrations remains at high levels. Thus, it is unclear if the reduced progesterone triggers the cervical ripening in term labor of women. Nevertheless, antiprogestins, such as mifepristone, can have a cervical ripening effect, and progesterone supplementation can reduce the rate of spontaneous preterm birth in women at high risk with a prior spontaneous preterm birth, indicating anti-ripening activity of progesterone.

Prostaglandin E2

Prostaglandin E2 (PGE2), a principal mediator of inflammation, plays a critical role in cervical ripening. Its biosynthesis in the cervix involves conversion of arachidonic acid to prostaglandin H2 (PGH2) by PGH2 synthase (PTGS2) and conversion of PGH2 to PGE2 by prostaglandin E synthase 2 (PTGES2). In preterm cervix, 15-hydroxyprostaglandin dehydrogenase (HPGD) is highly expressed repressing tissue PGE2 levels by converting PGE2 to inactive 15-keto PGE2. When term approaches, up-regulation of PTGS2 and down-regulation of HPGE concomitantly occur, increasing the local concentration of PGE2 in the cervix. PGE2 has been used as an effective medication to induce cervical ripening and labor.

Other ripening agents of cervix

Animal studies suggested that cervical ripening can be induced by other factors including estrogens, relaxin, nitric oxide donors, and hyaluronidase. However, these agents are shown to be ineffective in women, and thus not recommended for cervical ripening agents in labor induction.

Glossary

16S rRNA sequencing A laboratory method used to identify and compare bacteria present within given samples.

Adventitia The outermost connective tissue covering of any organ.

Asymptomatic Exhibiting no symptoms of disease.

Commensal An organism that benefits from living in a close relationship with other species without harming it.

Competitive exclusion An ability of microorganism to effectively compete for resources in the microenvironment with other microorganisms.

Copulative Relating to sexual intercourse.

Dysbiosis Microbial imbalance resulted from a depletion of healthy bacteria and an overgrowth of harmful bacteria.

Dysuria Pain, discomfort or burning during urination.

Homeostasis A proper balance of host immune response under normal physiological conditions.

Dyspareunia Pain occurring just before, during or after sexual intercourse due to medical or psychological reasons.

Lamina propria A layer of connective tissue that lies under the epithelium.

Microbiome A combined genetic material of microorganisms inhabiting particular microenvironment.

Microbiota A community of microorganisms (bacteria, archaea, fungi and viruses) inhabiting particular microenvironment (e.g., body site).

Mucosa A mucous membrane consisted of the epithelium and lamina propria that lies various cavities in the body.

Parturition Childbirth.

Premenarche Occurring in the period before the first menstrual period (menarche).

Postpartum Occurring in the period following childbirth.

Pyknotic Relating to pyknosis (condensation and reduction in size of a cell or its nucleus).

Stratified squamous epithelium A tissue consisting of several layers of epithelial cells in which the surface cells are flattened (squamous).

Introduction

The vagina is a component of the lower female reproductive tract (FRT), which is located between the cervix of the uterus and external genitalia, primarily the vulva. The external opening of vagina may be surrounded and partially closed by a hymen. The vagina functions as a female copulative organ and is a part of the birth channel during parturition. It also functions as an excretory canal during menses. The vaginal wall contains abundant connective tissue and two layers of smooth muscle (an inner circular and an outer longitudinal layer). The adventitia, the outermost connective tissue, is rich in elastic fibers and contains nerves and blood vessels that blend with the connective tissue of the pelvis. The adventitia fixes the vagina to surrounding tissue structures. The vaginal mucosa is lined with nonkeratinized stratified squamous epithelium, supported by thick lamina propria. The vaginal epithelial cells produce glycogen, which is both housed in the epithelial cells and secreted into the vaginal lumen. Glycogen supports the growth of commensal vaginal bacteria, such as lactobacilli, which acidify the mucosa and protect it against infection with invading pathogens. When the vaginal microbiota are disrupted, dysbiosis may occur. The outcomes of dysbiosis are detailed herein. The lining of vaginal cavity is also altered by sex hormones during the menstrual cycle and throughout a woman's lifespan (Muhleisen and Herbst-Kralovetz, 2016).

Gross Anatomy

The vagina is a fibromuscular, collapsed tube, when it is in a relaxed state. The lateral walls of the vagina are more rigid than anterior and posterior walls. Because of this, the vagina has a H-shaped cross section in the central portion. The length and shape of the vagina varies between women with an average length of 6.3 cm (2.5 in) (Barnhart et al., 2006). The vagina is located within the female pelvis, anterior to the rectum and the anus, posterior to the urinary bladder and the urethra and laterally to the ureter and uterine artery. It lies at a 45 degree angle in relation to the perineum, and 90 degree angle in relation to the uterus. The vagina is attached to the pelvic walls by ligaments and endopelvic fascia, a system of connective tissue. Protrusion of the cervix into vagina forms vaginal fornices, that is, recesses of vaginal vault, divided into two lateral fornices; anterior fornix and posterior fornix. The

posterior fornix is the deeper recess and is adjacent to the rectouterine pouch, whereas the smaller anterior fornix adjoins the vesico-uterine pouch (Standing, 2008).

Functional Anatomy

The vagina functions as a female copulative organ. During intercourse, this organ assists in receiving and transporting semen to the uterus. The vagina also provides a birth canal for the delivery of a fetus from the uterus and serves as a channel for menstrual fluid and tissue to leave the body. These physiological functions of the vagina require both lubrication and an elasticity to allow for expansion. The vagina does not have secretory glands, instead most of the vaginal lubrication comes from transudation of plasma mixed with cervical gland secretions (Dutta, 2014). Lubrication significantly increases with sexual arousal due to vascular engorgement of the vagina. The vagina is also lubricated, however diminutively, by two Bartholin's glands located in the vestibule on either side. During sexual arousal and intercourse, the vagina expands in length and width, while the cervix retracts, the elastic walls of the vagina stretch and contract with support of pelvic muscles, specifically the pubococcygeus muscle. The elasticity of the vagina is related to the large number of elastic fibers in the connective tissue of the wall and the extensive venous plexus. These features also allow the vagina to greatly increase its diameter to accommodate a fetus during parturition. The vaginal mucosa also displays distinct morphological structures, including microfolds (vaginal rugae), which provide the vagina with additional surface area to expand and these structures also serve to interlock the cell layers and hold mucus in place (Fedele et al., 2006; Ludwig and Metzger, 1976). The vaginal stratified squamous epithelium also functions as a physical barrier, which protects the body against invading pathogens. The vaginal mucosa tolerates commensal microbiota, which also play an active role in maintaining homeostasis and host defense. The growth of these microbes is supported by glycogen produced and secreted by vaginal epithelial cells. The commensal lactobacilli utilize glycogen and produce lactic acid, which decreases the vaginal pH (O'Hanlon et al., 2013). The acidic microenvironment coupled with the antimicrobial compounds produced by lactobacilli protects the vaginal mucosa against microbial insults.

Vascular Supply, Lymphatics and Innervation

Blood is supplied to the vagina by the vaginal and uterine arteries, which are branches of the internal iliac artery. The vaginal arteries anastomose with a branch of uterine artery to form azygos arteries of the vagina, which run longitudinally on the anterior and posterior of the vagina. The vaginal wall is highly vascularized with both a venous and arterial plexus. Two main veins drain blood from the vagina, located on both sides. Ultimately blood is drained into the internal iliac veins (Standing, 2008).

Lymphatic drainage occurs through the iliac and superficial inguinal lymph nodes. The upper vagina drains into the external iliac lymph nodes. The posterior vagina drains into inferior gluteal, sacral and anorectal lymph nodes, then ultimately in the internal iliac nodes. The distal vagina drains into superficial inguinal nodes (Standing, 2008).

The vagina receives innervation primarily from the sympathetic and parasympathetic nerves derived from the uterovaginal nerve plexus and the pudendal nerve. The inferior fibers from the uterovaginal plexus, which lies on each supravaginal sides of the cervix, supply the upper part of the vagina. These fibers are derived from the inferior hypogastric plexus and the pelvic splanchnic nerves (from sacral spinal cord levels S2–4) (Standing, 2008). The lower vagina innervation is carried through the pudendal nerve, which carries sympathetic, but not parasympathetic fibers. These autonomic efferent nerves supply the vaginal smooth muscles and vascular muscles, penetrating the lamina propria and epithelium. Somatic nerve supply is mainly to the lower portion of the vagina and is carried by the pudendal nerve to the sacral spinal cord (Standing, 2008).

Hormonal Regulation

In premenopausal women, the vaginal epithelium is under the influence of hormonal changes during the menstrual cycle. During the proliferative phase of the menstrual cycle, high levels of estrogen increase the thickness of the epithelium, glycogen production and mucus secretion. The vaginal epithelium thickens through estrogen-stimulated epithelial proliferation, stratification, and cornification. The apical epithelial layers consist of large, polygonal-shaped cells that are distinctly flat (Fig. 1). These superficial cells are not nucleated or their nuclei are pyknotic. Moreover, the multilayered epithelial cells accumulate glycogen in the cytoplasm. High levels of glycogen promote the growth of lactobacilli and production of lactic acid, which protects the vaginal mucosa against infections (Nunn and Forney, 2016). Due to the production of lactic acid, the pH level decreases and is directly correlated with free glycogen levels in vaginal secretions (Mirmonsef et al., 2016). During the secretory phase of the menstrual cycle, when estrogen levels are low, the epithelial thickness decreases due to continuous epithelial shedding (desquamation). Moreover, glycogen is less abundant within cells, which may result in increased vaginal pH.

Hormones also influence the vaginal mucosa through a woman's lifespan (Table 1). Prior to puberty women produce little estrogen, which results in low levels of glycogen and high vaginal pH. The vaginal mucosa prior to puberty in premenarchal women is composed of a thin, stratified squamous epithelium with anucleated cells on the top that are covered with a thin layer of mucus. In reproductive age premenopausal women with high levels of estrogen, glycogen deposits in the epithelial cells and free glycogen are increased and available for lactobacilli to thrive. During the premenopausal stage the vaginal epithelium is thickest and covered by a thick layer of mucus. During menopause, the levels of estrogen drops, decreasing glycogen and the vaginal epithelium

Fig. 1 A *Lactobacillus*-dominant vaginal microbiome promotes homeostasis, whereas a diverse non-*Lactobacillus*-dominant vaginal microbiome leads to dysbiosis. (A) High levels of glycogen, which is produced and secreted by the thick multilayered vaginal squamous epithelium, promotes lactobacilli growth. Lactobacilli produce lactic acid, which acidify the vaginal microenvironment, protects against infection, and maintain homeostasis. (B) Low levels of available glycogen can lead to depletion of lactobacilli and subsequent overgrowth of anaerobic and microaerophilic bacteria resulting in bacterial vaginosis (BV). The epithelium becomes thinner and atrophic. Lack of lactic acid results in increase in vaginal pH, and higher vulnerability to infections.

Table 1 Changes in the vaginal microenvironment during woman’s lifespan

Stage of life	Prior puberty/premenarchal	Reproductive age	Post menopause
Vaginal epithelium	Thin, dry	Multilayered, lubricated	Thin, dry/atrophic
Mucus	Thin layer	Thick layer	Thin layer
Estrogen level	Low	High	Low
Glycogen deposition	Low	High	Low
Microbiome	Diverse non- <i>Lactobacillus</i> dominant	<i>Lactobacillus</i> -dominant	Diverse non- <i>Lactobacillus</i> dominant
Vaginal pH	High (>4.5)	Low (<4.5)	High (>4.5)

resembles the prepuberty stage, with less layers and a thinner mucus layer (Muhleisen and Herbst-Kralovetz, 2016). The lack of estrogen and depletion of commensal lactobacilli following menopause impacts not only the vaginal epithelium, but also other layers of the vaginal tissue, including the loss of elasticity and rugae and ultimately leads to thinning of the vaginal walls. These microanatomical changes often culminate in vaginal symptoms associated with menopause (e.g., vulvovaginal atrophy, vaginal dryness), and can be restored by hormone replacement therapy.

Vaginal Microbiome

The vaginal microbiota (VMB) are defined as a community of commensal, symbiotic and pathogenic microorganisms that colonize the vagina. In the majority of healthy reproductive age women, the VMB is dominated by lactobacilli; although these bacterial communities can vary considerably between individuals and over time. Use of 16S rRNA sequencing revealed that the VMB can be classified according to the dominant bacterial species present. Five different community state types (CST) were proposed by Ravel et al. to characterize the VMB composition (Ravel et al., 2011). Four of these community types are dominated by *Lactobacillus* species. The most common CSTs, CST I, and CST III, are composed predominantly by *Lactobacillus crispatus* and *Lactobacillus iners*, respectively. VMB can also be dominated by *Lactobacillus gasseri* (CST II) and *Lactobacillus jensenii* (CST V). Women with these *Lactobacillus*-dominant VMB also exhibit low vaginal pH (typically <4.5). CST IV lacks a high proportion of lactobacilli and is defined as the diversity state dominated by anaerobic and microaerophilic bacteria and is correlated with higher vaginal pH

(>4.5). This heterogeneous CST can be divided into two sub-types: CST IV-A, which is characterized by a modest proportion of lactobacilli, along with low proportion of *Anaerococcus*, *Corynebacterium*, *Finegoldia*, or *Streptococcus*, and CST IV-B with high proportion of *Atopobium*, in addition to *Prevotella*, *Parvimonas*, *Sneathia*, *Gardnerella*, *Mobiluncus*, *Peptoniphilus* and other taxa (Gajer et al., 2012). Notably, several bacteria present in the CST IV-B are associated with bacterial vaginosis (BV). Interestingly, significant differences in the VMB composition between women of different ethnic groups are observed. The *Lactobacillus*-dominant VMB are widely prevalent in Asian and White/Caucasian women (80%–90%), however only 60%–70% of African American or Hispanic women have *Lactobacillus*-dominant VMB. The higher frequency of CST IV/BV in African American and Hispanic women may contribute to health disparities. However, it is unknown whether the differences in the VMB composition and rates of BV are related to socioeconomic, behavioral, environmental or genetic factors and this is an active area of investigation.

Not all VMB compositions are beneficial for the host. The diversity state type (CST IV), characterized by a depletion of lactobacilli and increase in anaerobic and microaerophilic bacteria, has been associated with adverse reproductive and obstetric health outcomes, including increased risk of acquiring sexually transmitted infections, pelvic inflammatory disease, endometritis, preterm birth, and spontaneous abortions (Martin and Marrazzo, 2016), whereas *Lactobacillus*-dominant VMB are associated with homeostasis and vaginal health (Fig. 1). Lactobacilli benefit the host by producing lactic acid, which acidifies the vaginal microenvironment and provides protection against genital infections. Furthermore, lactobacilli inhibit colonization of invading pathogens through competitive exclusion (i.e., an ability to effectively compete for resources in the vaginal microenvironment with other microorganisms). The protective effect of *Lactobacillus*-dominant VMB have also been attributed to hydrogen peroxide; however, production of this antimicrobial compound by lactobacilli in hypoxic conditions of the vagina remains controversial (O'Hanlon et al., 2013). Other metabolites (e.g., biogenic amines) produced by specific vaginal bacterial species can also impact the VMB structure, facilitating growth of anaerobes and microaerophiles and could further impact the local microenvironment (Nelson et al., 2015).

The VMB composition often changes over relatively short periods of time. Age, menstruation, estrogen level, smoking, intercourse, hygiene habits and other practices have been shown to significantly impact the VMB composition (Hickey et al., 2012). During the menstrual cycle the VMB structure is more stable when estrogen levels are high. Similarly, pregnant women, which also exhibit elevated levels of estrogen, have more stable VMB when compared to nonpregnant women (Romero et al., 2014). Furthermore, the VMB of pregnant women are more commonly dominated by *L. crispatus* and *L. iners*, and the diversity (non-*Lactobacillus*-dominant) state is rarely observed. The postpartum decrease in estrogen often results in less stability of the VMB structure (Nunn and Forney, 2016). Low levels of circulating estrogen prior to puberty and following menopause also results in the depletion of lactobacilli and the growth of diverse anaerobic and microaerophilic bacteria (Muhleisen and Herbst-Kralovetz, 2016).

Estrogen impacts the VMB composition through increasing the glycogen content in the vaginal epithelial cells. Glycogen, which is a storage form of glucose, has been shown to promote growth of lactobacilli (Mirmonsef et al., 2016). It is poorly understood how glycogen becomes available for lactobacilli in the vaginal lumen. Interestingly, vaginal lactobacilli are not capable of metabolizing glycogen, although these bacteria can utilize maltose and other glycogen breakdown products. Vaginal secretions contain α -amylase, an enzyme, which converts glycogen to maltose, maltotriose, maltopentaose, and maltodextrins that support lactobacilli growth (Spear et al., 2014). The origin of α -amylase in vaginal secretions remains unknown. However, it is hypothesized that α -amylase may be synthesized by other bacterial species co-inhabiting in the vagina with lactobacilli. In sum, both high levels of free glycogen and α -amylase are associated with *Lactobacillus*-dominant VMB.

Overall, *Lactobacillus*-dominant VMB are associated with vaginal health, and the disruption of the VMB appears to be a factor in the pathogenesis of several infectious diseases, including vaginitis and sexually transmitted infections. Host-vaginal microbiota interactions impact the local microenvironment through the production of soluble immune mediators (Doerflinger et al., 2014); these mechanisms influence outcomes related to vaginal health.

Disease

Primary lesions of the vagina, which are defined as a neoplasia that arises solely from the vagina, are relatively rare (1%–3% of gynecological malignancies) (Kumar et al., 2010). Most of these tumors (80%–85%) are squamous cell carcinomas, which are associated with high risk human papilloma virus (HPV) infections, similar to cervical cancer. Prior carcinomas of the cervix or vulva are also the greatest risk factors of vaginal squamous cell carcinoma. The Food and Drug Administration recommends HPV vaccination for girls and women before they become sexually active to prevent not only cervical cancer, but also vaginal cancer. Vaginal squamous cell carcinoma arises from the vaginal intraepithelial neoplasia (VAIN), a premalignant lesion characterized by the squamous cell dysplasia in the lining of vagina without invasion to the deeper tissue. This condition is generally asymptomatic; however, it can be detected by the presence of abnormal cells in the Papanicolaou test (Pap smear). This invasive cancer most often occurs in the posterior wall of the upper third of the vagina and metastasizes to the inguinal and iliac nodes. Adenocarcinoma, which arises from glandular cells of the vagina, is the second most common subtype (15%) of vaginal cancer. Other types include vaginal melanoma and two tumors mostly found in infants and children, that is, vaginal germ cell tumor, sarcoma botryoides. However, the most common vaginal malignancy is not the primary carcinoma, but metastatic squamous cell carcinoma from the cervix. Benign tumors of the vagina are also rare and include fibroepithelial (stromal) polyps, leiomyomas (smooth muscle neoplasia), and several cystic tumors (Kumar et al., 2010).

The majority of vaginal diseases are of microbial origin. Vaginitis is an inflammation of the vagina and possibly the vulva, which can result in itching or irritation, unusual discharge and pain or discomfort during intercourse (dyspareunia); however, some women exhibit no symptoms. Vaginitis is primarily caused by a disruption of normal vaginal microbiota (dysbiosis) or an infection with pathogenic bacteria, viruses or protozoan parasites. Other causes of vaginitis include the decrease in estrogen levels, for example, during menopause, breastfeeding or particular treatments that intend to decrease estrogen. The most common types of vaginitis include candidiasis, bacterial vaginosis (BV), aerobic vaginosis (AV), trichomoniasis, and atrophic vaginitis (Table 2). These entities can also co-occur, resulting in clinical and therapeutic implications.

Vulvovaginal candidiasis (VVC) is a fungal infection, which is due to an excessive growth of the yeast *Candida* in the vagina. This fungus resides in small amounts in the vagina and other parts of human body and is usually not associated with any signs of disease. The causes of *Candida* overgrowth are still not fully understood. The risk factors that have been associated with VVC include antibiotic use, diabetes, high levels of estrogen and genetic predispositions (Achkar and Fries, 2010). *Candida albicans* is the most common cause (76%–89%) of candidiasis in the vagina. However, infections with other *Candida* species (*Candida glabrata*, *Candida tropicalis*, *Candida krusei*, and *Candida parapsilosis*) have increased. These non-*Candida albicans* *Candida* (NCAC) species are now classified as emerging pathogens. The symptoms of VVC are itching, burning during urination (dysuria), dyspareunia and a thick, white, curdy, odorless vaginal discharge. Vulvovaginal inflammation (erythema and edema) can also occur, which results from leukocyte infiltration (Table 2).

BV is the most common vaginal infection and is characterized as a depletion of commensal lactobacilli and an overgrowth of anaerobic and microaerophilic bacteria, including *Gardnerella*, *Atopobium*, *Prevotella*, *Leptotrichia*, *Sneathia*, *Mobiluncus*, *Megasphaera*, and BV-associated bacteria (BVAB) 1–3 (Onderdonk et al., 2016). Importantly, BV has a high recurrence rate and is difficult to treat. Epidemiological studies strongly suggest that BV is sexually transmitted (Muzny and Schwebke, 2016). BV-associated bacteria can be found in male penile skin, urethra, and semen. Studies on women that have sex with women also showed that BV is associated with increased number of female partners or having a female partner with BV. It is still controversial whether new or recurring cases of BV are caused by a single species, for example, *Gardnerella vaginalis*, or a polymicrobial consortium of BV-associated bacteria (Muzny and Schwebke, 2016). Importantly, BV is associated with serious reproductive and obstetric sequelae, including preterm birth, spontaneous abortions, pelvic inflammatory disease, endometritis, increased risk of acquiring HIV and other sexually transmitted infections (Martin and Marrazzo, 2016). The symptoms of BV include a white or gray vaginal discharge with fishy odor and dysuria. Itching and vulvovaginal inflammation (irritation, redness, and swelling resulting from leukocyte infiltration) are uncommon; BV can be also asymptomatic. In clinical practice, BV is generally diagnosed using the Amsel criteria. Demonstrating three of the following four characteristics is considered to be necessary to diagnose BV: (1) high pH of vaginal fluid (>4.5), (2) thin homogenous vaginal discharge, (3) a fishy volatile amine odor when the discharge is treated with a potassium hydroxide solution (whiff test) and (4) a presence of squamous epithelial cells coated with bacteria (clue cells) in wet mount (Table 2). Alternatively, the Nugent score is used mostly in the research setting and is calculated by assessing the presence of large gram-positive rods (bacilli, *Lactobacillus* morphotype, scored 0–4), small gram-variable rods (coccobacilli, *Gardnerella* morphotype, scored 0–4) and curved gram-variable rods (*Mobiluncus* morphotype, scored 0–2) in vaginal secretion using Gram stain and microscopy. A total score between 0 and 3 is considered negative for BV, whereas score 4–6 is intermediate and score 7–10 is defined as BV (Nugent et al., 1991).

AV is characterized by a decrease in commensal lactobacilli and presence of dysbiotic VMB containing aerobic bacteria of intestinal origin, including *Escherichia coli*, staphylococci, streptococci and enterococci (Donders et al., 2017). These changes in VMB result in an increase in vaginal pH. Women with AV, in contrast to women with BV, exhibit increased levels of vaginal inflammation, characterized by leukocyte recruitment. Women with AV also present with a thin, reddish vaginal mucosa with possible erosions and ulceration, a thick mucoid discharge of yellow to green color and foul smell, and dyspareunia (Table 2). AV can be diagnosed using wet mount microscopy. Compared to wet mounts from women with BV, microscopic slides obtained from patients with AV show presence of leukocytes and immature or parabasal epithelial cells (small round epithelial cells with high nuclear to cytoplasmic ratio). Moreover, clue cells are not observed. The AV scoring system includes assessment of number of lactobacilli and coccoid bacteria, leukocytes (including toxic leukocytes showing lysosomal activity) and parabasal epithelial cells. Total scores represent, respectively, no AV (0–2), light (3–4), moderate (5–6) and severe AV (7–10) (Donders et al., 2017). An alternative diagnostic test for AV was proposed to be based on the activity of five enzymes in the vaginal secretions: hydrogen peroxidase, leukocyte esterase, sialidase, β -glucuronidase and coagulase, which indicate inflammation and the presence of particular bacterial species associated with AV or BV (Donders et al., 2017).

Trichomoniasis is a sexually transmitted infection (STI) caused by a protozoan parasite, *Trichomonas vaginalis*. The parasite preferentially infects the squamous vaginal epithelium; however, it can also reach the urethra and the endocervix (Menezes et al., 2016). Most of the infected women (70%) do not exhibit any symptoms. If symptoms occur, they include itching and soreness of the vagina and vulva, redness, dysuria, dyspareunia, discomfort in the lower abdomen and thin clear, white, yellowish or greenish, discharge with fishy smell (Table 2). Moreover, women with trichomoniasis may exhibit erythema and edema with petechial spots on the vaginal and cervical mucosa (strawberry cervix). Notably, trichomoniasis also increases the risk of HIV acquisition and is associated with adverse pregnancy outcomes (Menezes et al., 2016). Other sexually transmitted viral and bacterial agents that can cause vaginitis include human papilloma virus (HPV), herpes simplex virus (HSV), *Neisseria gonorrhoeae*, and *Chlamydia trachomatis*.

Atrophic vaginitis, also known as vaginal atrophy or vulvovaginal atrophy (VAA), is an inflammation of the vagina and the vulva, which results from a decrease in circulating estrogen levels. In postmenopausal women the low levels of estrogen cause

Table 2 The most common types of vaginitis

Diagnosis	Etiology	Associated species	Inflammation (leukocyte infiltration)	Vaginal discharge	Vaginal pH
Normal	Healthy <i>Lactobacillus</i> -dominant VMB	<i>Lactobacillus crispatus</i> <i>Lactobacillus gasseri</i> <i>Lactobacillus jensenii</i> <i>Lactobacillus iners</i>	No	No	< 4.5 (normal)
Vulvovaginal candidiasis	Yeast infection	<i>Candida albicans</i> <i>Candida glabrata</i> <i>Candida tropicalis</i> <i>Candida krusei</i> <i>Candida parapsilosis</i>	Yes	Thick, white, curdy without odor	< 4.5 (normal)
Bacterial vaginosis	Overgrowth of anaerobic and microaerophilic bacteria	<i>Gardnerella vaginalis</i> <i>Atopobium vaginae</i> <i>Prevotella</i> <i>Leptotrichia</i> <i>Sneathia</i> <i>Mobiluncus</i> <i>Megasphaera</i> BVAB 1–3	No	Thin, homogenous, white or gray with fishy odor	> 4.5 (increased)
Aerobic vaginitis	Overgrowth of aerobic bacteria of intestinal origin	<i>Escherichia coli</i> <i>Staphylococcus aureus</i> <i>Staphylococcus epidermidis</i> <i>Streptococcus agalactiae</i> <i>Enterococcus faecalis</i>	Yes	Thick, mucoid, yellow to green with foul odor	> 4.5 (increased)
Trichomoniasis	Parasitic infection	<i>Trichomonas vaginalis</i>	No/Yes ^a	Thin, clear, white, yellowish or greenish with fishy odor	> 4.5 (increased)
Atrophic vaginitis	Low level of estrogen	—	Yes	No discharge	> 4.5 (increased)

^aAsymptomatic vs. symptomatic.

microanatomical changes of the vagina, which include thinning of the vaginal epithelium, shrinking of the vaginal walls, and decreased lubrication. VVA symptoms consist of vaginal dryness, soreness and dyspareunia that impact quality of life and sexual health. The VMB structure can also attribute to the severity of disease (Muhleisen and Herbst-Kralovetz, 2016). Women with more diverse VMB, which are not lactobacilli-dominant, exhibit more severe signs and symptoms, when compared to women with lactobacilli-dominant VMB. The VVA symptoms can be improved by hormone replacement therapy. Estrogen administration not only improves vaginal symptoms, but also promotes growth of lactobacilli and improves vaginal health. Probiotics have also been shown promise to restore a healthy vaginal microbiome; however, more robust clinical studies are needed to determine efficacy and safety of these novel therapeutics (Muhleisen and Herbst-Kralovetz, 2016).

Embryology

In the 6th week of human embryonic development, the sexually undifferentiated embryo possesses two pairs of genital ducts, the Wolffian (mesonephric) and Müllerian (paramesonephric) duct. Only one of the ducts reaches complete development, depending upon the sex, i.e., if the embryo is supposed to become a female, the Müllerian ducts develop and vice versa. Initially, the Müllerian ducts are separate, but later, they fuse together to form the uterovaginal canal (Fig. 1); and this uterovaginal canal further extends towards the caudal opening called the urogenital sinus (Figs. 2 and 3). By the end of the 3rd month of embryonic development in human, the fusion septum of the two Müllerian ducts starts to recede, and a single uterovaginal canal is formed (Figs. 2 and 3). Proliferation of the endoderm at the urogenital sinus results in the sinovaginal bulb formation (Figs. 1A, 2A and B, 3A and B), which stretches from the urogenital sinus to the uterovaginal canal. Later the sinovaginal bulb (plate) expands and forms the major portions of the vaginal primordium. The upper one-third of the vagina originates from the uterovaginal canal (Müllerian duct), while the lower two-thirds develops from the endoderm of the sinovaginal bulb (urogenital sinus). On the other hand, the fibromuscular wall of the vagina evolves from the splanchnic mesenchyme that surrounds the epithelium of the developing vagina. The vaginal orifice is covered with a membrane called hymen, and this hymen marks the junction between sinovaginal plate and urogenital sinus (Figs. 2 and 3). Although the hymen ruptures in the perinatal period, a portion of it remains as a thin fold of tissue, located just within the vaginal entrance.

At the time of birth, the stratified squamous epithelium lining the vagina ranges from 6 to 10 cells in thickness. Although, the vaginal epithelium remains comparatively thin during childhood, it later thickens at puberty, due to the estrogenic stimulation. The epithelial thickness varies, depending upon the menstrual cycle, pregnancy, and atrophies. Interestingly, after menopause, the epithelial thickness reverts back to its initial thin prepubertal state.

In mice, the Müllerian duct formation and differentiation are well investigated. After the Wolffian duct formation, the progenitor cells associated with LIM (Lin11/Isl1/Mec3) class homeodomain transcription factor (LHX1) expression are formed in the mesonephric epithelium at the upper end of the urogenital ridge at embryonic day (E) 11.5. These Müllerian duct cells invaginate caudally into the mesonephros and then elongate along the Wolffian duct to the urogenital sinus derived from the endoderm. This elongation completes by E13.5. Wnt4 expression in the mesonephric mesenchyme is necessary for Müllerian duct cells invagination. While the upper Müllerian ducts are separated both right and left sides, elongated each Müllerian duct is joined and fused

after they cross over the Wolffian ducts. This fused caudal portion of the Müllerian duct develops into the upper three-fifth of the vagina, and the urogenital sinus develops into the lower vagina. After birth, the epithelium of the Müllerian vagina migrated towards the posterior, and the epithelium of the urogenital sinus remains in the vulva when the vagina is opened for puberty. Tissue recombination studies reveal that the each epithelium-specific phenotype can be induced by the local factors from the surrounding mesenchyme. Fibroblast growth factor 7/10, bone morphogenetic protein 4 and activin A can act as paracrine factors to stimulate vaginal epithelial cell differentiation. Thus this reflects that the epithelial cells have plasticity, however it is restricted to the first week of postnatal development.

Histology

The vaginal wall consists of the tunica mucosa or mucosa, tunica muscularis or muscularis, and the tunica adventitia or adventitia (Fig. 4).

Tunica Mucosa

The mucosa consists of the lining epithelium and the underlying lamina propria (connective tissue). A nonkeratinized stratified squamous epithelium shows 150–200 μm thick and can be classified into type II mucosa. Human vaginal epithelium is less prone to hormonal fluctuations during the menstrual cycle as compared to other species. In humans, during the follicular phase, when the estrogen level is at peak, the vaginal epithelial thickness rises up to 45 cells thick, while during the luteal phase, which is marked by low estrogen and high progesterone amount, the epithelial layer is reduced to about only 30 cells thickness (Fig. 5). The glycogen content of the epithelial cells is an important factor and is known to vary with the menstrual cycle. The epithelial cells are rich in glycogen during the mid-cycle, probably under the estrogenic influence, (Fig. 5), but the amount reduces significantly in the latter

phase of the cycle. The epithelial cells are interconnected together, primarily in the basal layers, by several mechanical adherent junctions and communication junctions called desmosomes and gap junctions, respectively. However, at the superficial layers, several tight junctions are present which form a sort of permeability barrier for the larger water-soluble molecules. The intercellular spaces between the epithelial cells which facilitate the unobstructed movement of blood-derived mononuclear leucocytes, especially the lymphocytes. The epithelial cells are also involved in the immune response of the vagina.

Toll-like receptors (TLR), important for the innate vaginal immunity, are expressed in the surface of vaginal epithelial cells. Epithelial cells produce molecules showing nonspecific antimicrobial activity. Defensins can bind negatively-charged bacterial cell surfaces and disrupt microorganism membrane. Secretory leukocyte protease inhibitor (SLPI) inhibits proteases and protects the epithelium from the bacteria and viruses action. Mannose-binding lectin (MBL) induces the direct lysis of bacteria by binding mannose residues, *N*-acetylglucosamine and fucose in the surface of microorganisms. Various immune cells are also distributed in the vagina. T cells, natural killer (NK) cells and macrophages/dendritic cells are dominant. Components of immune cells are similar in the vagina during the menstrual cycle unlike those in the uterus.

Vaginal epithelial cells secrete mucus, which consists of mucins, to protect the epithelial cells against infectious microorganisms. The amount of MUC5B protein in mucus and its glycosylation are increased during ovulation. In addition, the mucus structure is changed at the time of ovulation. Mucus in the vagina is known as sialoglycan-rich proteins, negatively charged hydrophilic carbohydrates. Sialoglycoproteins play roles in protecting from bacterial infection.

The lamina propria, which lies subjacent to the epithelium, is composed of dense connective tissue layers, with several elastic fibers running through it to the underlying muscles. Interestingly, the lamina propria gradually becomes less dense as it approaches the muscle. The lamina propria is composed of several large thin-walled veins (Fig. 4), bound together in a grid and giving the appearance of an erectile tissue. Since the lamina propria is devoid of any glands, the vagina obtains much of its lubrication from the glands of the uterine cervix. However, the rich vascularization of the vagina is also known to serve as a fluid source that helps the fluids to seep through the squamous epithelium during sexual stimulation. Vaginal elasticity is often related to the massive network of elastic fibers in the connective tissues of its wall and its extensive venous plexus.

Tunica Muscularis

The tunica muscularis layer is composed of numerous loosely arranged, spiraling bundles of smooth muscle cells (Fig. 4). The smooth muscles, in addition to the spiral bundles, are also comprised with several inner circular and outer longitudinal layers. A multitude of skeletal muscle fibers (bulbospongiosus muscle) are also present at the vaginal opening, forming a sphincter.

Tunica Adventitia

The thin layer of connective tissue that is rich in elastic fibers, and merges with the connective tissues of the urethra, rectum and anal canal is known as the tunica adventitia (Fig. 4). Countless nerve bundles travel through the adventitia in order to reach the muscle and mucosa layers.

Cytology

It is of paramount importance to understand the effect of various endogenous and exogenous hormones on the vaginal epithelium and the ovaries in order to get a comprehensive idea of their functioning in the female body.

Since the cellular differentiation takes place in the vaginal epithelium, the superficial epithelial cells differentiate continuously and are shed during the menstrual cycle, with the greatest desquamation happening at the latter part of the luteal phase and during menstruation. Vaginal smears are the best indicators (based on the cytology of cells) of the functional state of the ovaries (in regard to the secretion of hormones). Thus, the morphological studies of the cells collected from vaginal smears, especially the different types of cells from the most superficial layer of the epithelium, provides the most accurate information for clinical examination, such as the presence of leukocytes in case of early cancer detection (Pap smear; Papanicolaou and Traut, 1943).

The desquamation of superficial cells is more pronounced shortly before the onset of menstruation, particularly during the mid-cycle or premenstruation. Although, the superficial cells become relatively smoother during the first trimester of pregnancy, it later becomes highly fragmented in the postmenopausal phase. The vaginal smear shows signs of continuous exfoliation of single superficial cells, as the female ages. The size of superficial vaginal cells varies with age; larger cells being more profound in young women (17 years), while the smaller sized cells are found in older women (47 years). However, after menopause, the normal vaginal mucosa consists of a thin squamous epithelium with basal cells and no glycogen content.

In rodents, vaginal smears have been also used for microscopic examination to evaluate the estrous cycle (Fig. 6). Generally, the estrous cycle is separable into four stages, proestrus, estrus, metestrus, and diestrus. Three basic cell types are found in the vaginal smears, leukocytes, epithelial cells with smooth margins and keratinized cells. On the morning of the day at proestrus, high levels of estrogen stimulates the LH surge, resulting in ovulation. Epithelial cells, but not leukocytes, can be found in the vaginal smears. Estrogen stimulates the cornification and keratinization of vaginal epithelial cells, therefore, keratinized cells are dominantly found in the vaginal smears at estrus. After ovulation, keratinized cells are reduced but leukocytes are infiltrated at metestrus, while absence of keratinized cells and leukocytes dominance are detected at diestrus.

(1966). *General Endocrinology* (4th edn.). Philadelphia: W.B. Saunders Company.

Hormonal Influence

The vaginal epithelium, during the functional reproductive years with an active sex life is under normal estrogen stimulation, and is thickened and slightly cornified but not keratinized in structure. However, during the proliferative phase (follicular stage) of the menstrual cycle, the estrogen level rises, the superficial epithelial cells become large and flattened with pyknotic nuclei, and the cytoplasm show increased acidophilia and glycogen accumulation. The estrogen stimulation peaks at midcycle and maximum epithelial thickness and glycogen accumulation is observed (Fig. 5B). At this stage, the lactic acid bacteria ferment the glycogen of desquamated cells to lactic acid, resulting in a decrease in pH of the vaginal fluid which is helpful in resisting infections. Although when the estrogen content decrease in the secretory phase (luteal) of the cycle, the epithelial layer gradually loses its thickness due to sloughing of surface cells. The appearance of the desquamated cells become irregular and elongated with folded and curled edges. The glycogen content of the cells also becomes less abundant; resulting in an increase in pH of vaginal fluid which enhances the chances of infections.

The administration of exogenous estrogen is an efficient therapeutic strategy for vaginal infections owing to its profound influence on the vaginal epithelium. On the contrary, excess estrogen causes hyperestrogenism which increases the thickness of the epithelial layer along with intense cornification and exfoliation of epithelial cells, and higher acidic pH of the vaginal fluid. Hypoestrogenism, is the reverse of hyperestrogenism, wherein increased pH of the vaginal fluid increases and epithelial atrophies are observed.

Ovarian hormones, 17β -estradiol (E2) and progesterone, can bind the specific nuclear receptor superfamily, estrogen receptor (ER) and progesterone receptor (PR). Mammalian ER has two distinct forms, ER α and ER β , and since ER α knockout mice do not respond to E2 stimulation, it emphasizes the essential roles of ER α in the reproductive tracts. In mice, ER α mRNA and protein are detected in the vaginal epithelium and stroma from the fetal age through the adult and its roles in the epithelium and stroma is

investigated by both tissue recombinant and knockout techniques. The vaginal epithelial cell proliferation stimulated by E2 is mediated through stromal ER α , but not by the epithelial ER α . Both epithelial and stromal ER α are necessary for E2 responsive epithelial cornification in the vagina. ER α in the vaginal epithelium is also necessary for the switch between E2-dependent cell proliferation and squamous cell differentiation. On the other hand, ER β mRNA and protein are also expressed in the vaginal epithelium during neonatal period, however, they decrease with age in mice. The role of ER β in reproductive tracts is considered to inhibit cell proliferative action stimulated by E2.

PR has two natural isoforms, PRA and PRB, which are transcribed from the same gene. PR mRNA and protein are detected both in the epithelium and stroma of the vagina, however, ovariectomy reduces epithelial PR in mice. E2 also directly induces PR expression in the vaginal epithelium and stroma. Progesterone stimulates epithelial cell differentiation but inhibits cell proliferation of the vaginal epithelium. Tissue recombination studies reveal that stromal PR, not the epithelial PR, is essential to mediate the inhibitory effect of progesterone on epithelial cell proliferation, especially upon E2 stimulation.

Additionally, the phosphatase and tensin homolog deleted from chromosome 10 (Pten), a tumor suppressor gene, plays a vital role in the epithelial cell homeostasis of the mouse vagina. Ovariectomy reduces the epithelial cell layers, and Pten is expressed in the suprabasal cells to inhibit abnormal cell proliferation and differentiation.

Innervation

The autonomic nervous system and the pudendal nerve innervates the vagina, while the parasympathetic supply to the vagina is through the pelvic splanchnic nerves (from sacral spinal cord levels S2–S4 in human) and the uterovaginal plexuses. The abdominal sympathetic trunks continues caudally into the pelvis, passes over the ala of sacrum and converges into the ganglion impar near the vertebral level S5. Two or three sacral splanchnic nerves supply the inferior hypogastric plexus, and mixed branches from the inferior hypogastric plexus connects the internal iliac artery to the vagina. Additionally, the pudendal nerve furnishes the utero-vaginal plexus with the general visceral efferent fibers.

The smooth and vascular smooth muscle of the vagina are supplied with several fibers from the utero-vaginal plexuses, which are autonomic efferent in nature and travel through and in the lamina propria. Some of these intraepithelial nerve fibers are quite discernable and appear as free nerve endings among the epithelial cells. Although some fibers are successful in penetrating the surface of the epithelium, most of them end among the basal two-thirds of the epithelium. These fibers are located mainly near the introitus of the vagina and are nociceptive in nature.

The lamina propria and tunica muscularis are composed of more dense nerve fibers than the epithelium, with the anterior vaginal wall having more fibers than the posterior wall. The anterior vaginal wall also has a lower threshold level to pain stimulation as compared to the posterior wall. The vaginal nerve fibers utilize a variety of classical (catecholamine and acetylcholine) and nonclassical neurotransmitters (neuropeptides and nitric oxide), especially the neuropeptides like neuropeptide Y (NPY), calcitonin gene-related peptide (CGRP), substance P (SP) and vasoactive intestinal polypeptide (VIP). All the above substances are not only abundant in the nerves close to arteries and capillaries in the connective tissue papilla (Fig. 4), several neuropeptides and nitric oxide are also known to influence the capillary permeability and blood flow. The higher VIP content in the vagina results in increased vaginal exudation (vaginal fluid production) rate and blood flow during sexual arousal, along with reduced postmenopausal effects. Vasodilators like CGRP and SP are usually associated with sensory nerves, while NPY is known to potentiate the vasoconstrictor activity of noradrenaline.

The pudendal nerves provides the lower vagina and presumably influences the somatic pain in the lower vagina.

Pathology

Bacteria inhabit the vaginal cavity are thought to be maintain vaginal homeostasis. Imbalance or disruptions of vaginal flora are associated with pelvic inflammatory disease, miscarriages, and prematurity. The bacteria *Lactobacillus* spp. is dominant in the normal flora of the vagina in most women. *Lactobacillus* is responsible for production of lactic acid from glycogen by fermentation, resulting in the maintenance of low pH of the vagina and protection against the growth of pathogenic bacteria. Levels of *Lactobacillus* are correlated with free glycogen levels in genital fluid. *Lactobacillus* in the vagina also produces hydrogen peroxidase, which is toxic to pathogens. Infections of viruses (herpes simplex virus and human papilloma virus), fungi (*Candida albicans*) and the bacterium result in diseases of the vagina, vaginitis. Addition to the low pH in the vagina by *Lactobacillus* spp., it is reported that bacteriocidal and bacteriostatic proteins (bacteriocins) can inhibit the growth of pathogens. Maternal vaginal microbiome also contributes to the intestinal colonization of neonates by exposure in the time of delivery. The bacterial composition of the vagina changes across the female lifespan, from prepuberty to postmenopausal women. Prepuberty and postmenopausal women show lower levels of *Lactobacillus* spp. Estrogen can stimulate the accumulation of glycogen in the vaginal mucosa and the growth of *Lactobacillus* spp., therefore, the vaginal microbiota is under the influence of sex hormones. Exogenous factors such as contraceptives, sexual intercourse, showers, deodorant products, antibiotics and medications can alter the composition of the vaginal microbiota as well as endogenous factors.

Müllerian duct anomalies are caused by disruption of normal development of the Müllerian ducts during embryogenesis. Failure of the Müllerian duct fusion developmentally results in duplication of the vagina, which may be associated with a transverse vaginal

Fig. 7 Main abnormalities of the uterus and vagina, caused by persistence of the uterine septum or obliteration of the lumen of the uterine canal. Reproduced with permission from Sadler, T. W. (ed.) (2015). *Langman's Medical Embryology* (13th edn.). Philadelphia: Wolters Kluwer.

septum (Fig. 7). The partial or complete uterovaginal septum is caused by a failure of septum reabsorption. Lack of the development of the sinovaginal bulb or canalization of the bulb results in the absence of a vagina. Congenital absence of the uterus and two-third of the upper vagina, known as Mayer-Rokitansky-Küster-Hauser syndrome, is Müllerian agenesis. While it has not been revealed molecular mechanisms yet, involvement of several genes including *Hoxa* and *Wnt4* with Mayer-Rokitansky-Küster-Hauser syndrome has been reported. Faulty development of an urorectal septum results in an abnormal connection between the rectum and the vagina (rectovaginal fistula). Damage (e.g., during childbirth) to the supporting structures (Transverse cervical, pubocervical, and sacrocervical ligaments) of the uterine cervix, and thus the vagina, within the pelvic cavity can lead to prolapse of the vagina (exposure to the exterior).

Vaginal Cancer

Diethylstilbestrol (DES), a synthetic nonsteroidal estrogen, synthesized in 1938 has been used for the prevention of miscarriages as well as some of the later complications of pregnancy, since 1940. In 1971, Herbst et al. discovered the association of DES usage during pregnancy and the occurrence of vaginal clear cell adenocarcinoma in a small percentage of exposed daughters. Moreover, studies on mice, exposed prenatally and neonatally to exogenous estrogens, have revealed similar types of vaginal cancers in 1963–64 (Dunn and Green, 1963; Takasugi and Bern, 1964).

Prenatal exposure to DES and related drugs, causes vaginal and cervical adenocarcinoma in women. Several nonneoplastic abnormalities of the vagina and cervix, such as cervical ectropion (erosion and eversion), and vaginal adenosis, both of which are commonly accompanied by squamous metaplasia, as well as variety of gross malformations, were found in women after intra-uterine exposure to DES. Cervical ectropion, defined as the presence of glandular (columnar) epithelium or its mucinous products in the ectocervix, is a common phenomenon (40%–65%) in women who have not been exposed to DES. However, these lesions are encountered in over 95% of DES-exposed women. Vaginal adenosis is defined as the presence of glandular (columnar) epithelium or its mucinous products in the vagina. These lesions are noted in 3%–13% of unexposed women, and in 35%–90% of DES-exposed women.

Mice exposed prenatally or neonatally to estrogen including DES, developed squamous cell carcinoma in the vagina and/or cervical regions. Higher dosages of estrogen exposure during perinatal life induced ovary-independent vaginal cornification, lesions, and tumors. The squamous cell carcinoma induced by neonatal estrogen exposure was transplantable serially for many generations.

Introduction

After receiving the LH signal, Graffian follicles in the ovary are induced to ovulate. The product of this ovulation, the female gamete, the oocyte, is collected in the oviduct. In all mammals, prior to ovulation, the oocyte is arrested in the cell cycle at the prophase stage of the first meiosis, which is also known as the germinal vesicle (GV stage). Following the LH surge, the oocyte resumes meiosis and progresses to the metaphase stage of the second meiosis, the MII stage, where it undergoes a second arrest and where fertilization takes place. Fertilization can be defined as the union of two haploid gametes, the spermatozoa and the oocyte, hereto referred to as egg, to restore the diploid state, form a zygote through the process of egg activation, and commence a series of mitotic divisions that results in cell differentiation and embryo development.

Fertilization takes place in a region of the oviduct named the ampulla. The initial interaction of the gametes is mediated by the glycoprotein components of the zona pellucida (ZP), ZP1–3 in the mouse and ZP1–4 in humans, in the egg, and an unknown cognate sperm receptor (Avella et al., 2013). The sperm then powers its way through the ZP entering the perivitelline space, which is the space between the ZP and the egg's plasma membrane (PM), the oolema. A sperm protein, Izumo, and several egg proteins including Juno, formerly Folr4, which is the receptor for Izumo, and CD9 and CD81, which are tetraspanins involved in the organization of the oolema, are required for the fusion of mammalian gametes (Grayson, 2015), although their precise role in the fusion process is unclear. Following fusion, the sperm triggers the first stage of embryo development, the zygote, through a process known as egg activation, which consists of a multilayered series of events that transforms this meiotic, haploid, and transcriptionally inactive cell into a diploid and mitotically competent early embryo. The events of activation are initiated by an increase in the intracellular concentration of free calcium (Ca^{2+}) in the egg (Stricker, 1999; Wakai et al., 2011). In this article, we will review the molecular events underlying the main steps of egg activation, the signaling mechanisms responsible for the increase in Ca^{2+} and the consequences on fertility from failure to initiate these responses.

Events of Egg Activation

Besides introducing the paternal genome, fertilization induces egg activation, which consists of a series of biochemical and structural changes that transform the female gamete into a zygote. These events include the release of cortical granules (CGs) and prevention of polyspermy, the resumption and completion of meiosis, and the progression into interphase with pronuclear (PN) formation (Florman and Fissore, 2015) (Fig. 1). In most species and in all mammals, an increase in the intracellular Ca^{2+} concentration is the universal signal for egg activation (Stricker, 1999). Downstream effectors in the egg decode the spatiotemporal information provided by the Ca^{2+} signal and transform it into the distinct cellular events of egg activation that will be described later (see also Wakai et al., 2011, p. 42).

Prevention of Polyspermy

At fertilization, eggs are exposed to multiple sperm but entry of more than one sperm causes polyploidy, polyspermy, which results in abnormal embryo development. To ensure fusion of a single sperm, the egg becomes rapidly intolerant to additional sperm. It accomplishes this by developing a block to polyspermy, which consists of the ZP and PM blocks (Avella et al., 2013). The relative contributions of these two blocks vary in different species, with the PM block unfolding earlier than the ZP block. The PM block prevents binding/fusion of additional sperm, as evidenced by the presence of unfused sperm within the perivitelline space. The underlying molecular mechanism of this block remains unknown, although it lacks the membrane depolarization component present in marine eggs (Igusa et al., 1983). Remarkably, the PM block is deployed after fusion of the gametes in MII eggs but not after ICSI, suggesting that fusion is essential for this process. The recently identified Izumo receptor, Juno, might be involved, as it is shed from the oolema only after spontaneous fertilization either in vivo or in vitro (Bianchi et al., 2014). Nevertheless, how it is released from the oolema and its action to prevent additional fusions require additional characterization.

The ZP block is intended to prevent additional sperm penetration and/or binding of the ZP. Several mechanisms have been proposed to account for this block, including those that might cause changes in sperm-binding residues or changes in the organization of the zona or of its components (Avella et al., 2013). The most established model, which is based on the observation that ZP2, one of the main components of the ZP, undergoes cleavage after fertilization thereby eliminating the site(s) of sperm binding

Fig. 1 Schematic of the sequence of events of egg activation following fertilization in mammals. A typical pattern of Ca^{2+} oscillations initiated by fertilization or by injection of $\text{PLC}\zeta$ cRNA (recordings were terminated prematurely). The Ca^{2+} signals are decoded by downstream protein kinases, including MLCK, CaMKII, MPF, MAPK, and Plk1. *Full arrows* denote molecules and pathways whose function have been demonstrated by inhibitors or genetic models, whereas *broken arrows* indicate tentative pathways and/or molecules whose participation/role requires additional confirmation. PPase, denotes phosphatase. Other abbreviations are explained in the body of the article. From Ducibella T, Fissore R. The roles of Ca^{2+} , downstream protein kinases, and oscillatory signaling in regulating fertilization and the activation of development. *Developmental Biology* 2008;315:257–279.

located on the N-terminal portion of the molecule. A component of the GC exudate, which is exocytosed into the perivitelline space following the Ca^{2+} oscillations, is responsible for this cleavage. Ovastacin has been identified as the CG's ZP2 protease, and eggs null for the *Astl* gene, which encodes for ovastacin, failed to cleave ZP2 and allowed continuous ZP binding and penetration (Burkart et al., 2012). In vivo, ovastacin action is inhibited by the liver-derived plasma protein fetuin-B, which is part of the cystatin superfamily and related to protease inhibitors, as eggs of *Fetub*^{-/-} mice showed preovulatory ZP2 cleavage that prevented sperm penetration of the ZP rendering these females infertile (Dietzel et al., 2013).

Little is known about the mechanism underlying the dynamics of CG exocytosis during egg activation, although their release requires Ca^{2+} release. Moreover, a Ca^{2+} and calmodulin (CaM)-dependent enzyme, myosin light chain kinase (MLCK2), and its direct target myosin II are involved in CG exocytosis, as their inhibition impairs CG release (Simerly et al., 1998). Given that MLCK is regulated by phosphorylation (Deng et al., 2005), the kinase(s) involved in its regulation need(s) to be determined. The role of molecules such as Rab3 and synaptotagmins on GC release also needs to be established. Another event that occurs in close association with CG release is the efflux of zinc, which is known as zinc sparks (Kim et al., 2011). The zinc sparks arise from zinc-loaded vesicles that have similar distribution to CGs. Its release may facilitate exit of MII and contribute to the polyspermy block, as ovastacin is a zinc-dependent enzyme and high concentrations of zinc in the perivitelline space induce changes in the organization of the ZP that prevent polyspermy (Que et al., 2017).

Exit of Meiosis and Resumption of the Cell Cycle

Most vertebrate oocytes undergo maturation and become arrested until fertilization at the MII stage of meiosis. Fertilization triggers completion of meiosis, establishment of euploidy and the start of embryonic cell cycles. The MII arrest is imposed by the action of the cytosstatic factor (CSF) (Masui and Markert, 1971). CSF constrains the activity of the anaphase promoting complex (APC/C), an E3 ubiquitin ligase (Tunquist and Maller, 2003), which is responsible for the ubiquitination and degradation of cyclin B (CycB) and of the separase's inhibitor securin that prevents sister chromatid separation (Madgwick et al., 2004). CycB and the cyclin-dependent kinase 1 (Cdk1, also known as cdc2) are the molecular components of the maturation-promoting factor (MPF) (Swenson et al., 1986), and inhibition of CycB degradation, which maintains high activity of MPF, makes possible the arrest at the MII stage (Masui and Markert, 1971). The endogenous meiotic inhibitor 2 (Emi2), a component of CSF (Tung et al., 2007), is the direct inhibitor of the APC/C (Sako et al., 2014), and exit of the MII arrest is brought about by SCF/proteasome-dependent degradation of Emi2 triggered by the fertilization-induced Ca^{2+} increase (Hansen et al., 2006). Although the precise molecular mechanisms in mammals remain to be elucidated, the degradation of Emi2 is caused by sequential phosphorylation events: the first one mediated by the Ca^{2+} -CaM-dependent protein kinase II (CaMKII) followed by a Polo-like kinase 1 (Plk1) phosphorylation (Jia et al., 2015). The activation of the APC/C reduces the levels of active MPF, which causes completion of the second meiotic division displayed as the extrusion of a second polar body and the progression into interphase with PN formation.

The Formation of the Pronuclei and DNA Synthesis

While eggs complete the second meiotic division following fertilization, the sperm DNA undergoes dynamic changes in chromatin structure. The sperm chromatin is tightly packaged due to its association with protamines, which are basic proteins with extensive disulfide bond formation. This association creates a toroid complex that results in transcriptional silencing (Balhorn, 1982), which must be reversed after fertilization. This process is coordinated by factors in the ooplasm such as glutathione, which reduces the protamine's disulfide bonds (Perreault et al., 1984), and by several proteins including the mammalian homologues of the chaperone protein nucleoplasmin (NPM), NPM1, NPM2, and NPM3, which assist with the removal of protamines and deposition of histones onto the paternal chromatin (Burns et al., 2003). Approximately 4–6 h after sperm entry, and almost simultaneously, a nuclear membrane encloses the decondensed male and female chromatin forming two PNs that contain the sets of haploid genomes. This process is dependent on ATP and GTP, and relies on the extensive egg reserves of endoplasmic reticulum membranes to generate the large surface area of the PNs (Byrne et al., 2009). Formation of PNs is associated with progressive inactivation of the MAPK pathway, which occurs 2–4 h later than the decline in MPF activity, although it is not known how MAPK influences the timing of PN formation (Gonzalez-Garcia et al., 2014). The protracted formation of PNs in mammalian zygotes may be necessary nevertheless to support the remodeling of the sperm chromatin, which may be halted or incomplete in cases of premature PN formation.

During the PN stage, both sets of chromatin undergo asynchronous DNA synthesis and differential epigenetic reprogramming including changes in DNA methylation, which the paternal genome experiences prior to and during the first DNA replication. In contrast, the female genome maintains a stable methylation level during the zygote stage, although it undergoes passive demethylation over subsequent cleavages (Wossidlo et al., 2010). The male PN is also hypomethylated and contains histone marks present in active promoters such as H3K4me3, whereas repressive histone methylation markers are mostly absent (Lepikhov et al., 2010). Conversely, these repressive histone methylation markers can be detected in the female PN. As DNA synthesis and epigenetic reprogramming proceeds, PNs undergo migration so that they become apposed. Actin microfilaments and microtubules are required for pronuclear apposition in mouse eggs, although in humans and other large domestic animals, pronuclear migration and apposition relies exclusively on microtubules (Payne et al., 2003, p. 65). The two nuclear envelopes break down without fusing, and the centrosome splits to organize a bipolar spindle. The condensed chromosomes of both male and female origin align along the spindle equator. A cleavage furrow forms at the first mitotic anaphase and telophase. The completion of mitosis gives rise to two embryonic cells, each containing a new diploid genome. For a more detailed discussion of other events of egg activation and fertilization such as recruitment of maternal RNAs, please refer to exhaustive reviews on the subject (Ducibella and Fissore, 2008; Florman and Fissore, 2015; Schultz and Kopf, 1995).

The Signal for Egg Activation

Ca²⁺ Triggers Development

An increase in the levels of free Ca²⁺ in the female gamete is the earliest and universal signal of egg activation. Work by Loeb and colleagues at the end of the nineteenth century associated egg activation with changes in the intracellular concentration of several ions (Loeb, 1899), and later studies demonstrated that the divalent cation Ca²⁺ was the responsible ion. Ca²⁺ is able to induce a multitude of cellular events because it alters the function of proteins by changing their charge and shape (Clapham, 2007). The actions of Ca²⁺ are also favored by: (1) the steep gradient between its intracellular and 10,000-fold greater extracellular concentration; and (2) the energy-dependent mechanisms that cells dedicate to restore intracellular Ca²⁺ levels to ~100 nM, which is the basal level in most cells (Clapham, 2007). Ca²⁺ ionophores, which can mobilize Ca²⁺ across membranes and along concentration gradients, are effective means of inducing egg activation (Steinhardt et al., 1974). Two common targets of Ca²⁺ in all cells, which are abundantly expressed in eggs, are CaM and the Ca²⁺-CaM-dependent kinase II, CaMKII (Ducibella and Fissore, 2008). In support of this signaling cascade, eggs lacking CaMKIIγ3, which is the isoform expressed in mammalian eggs, fail to exit the MII stage following fertilization despite having normal oscillations (Backs et al., 2010).

In all mammals, the initial activating Ca²⁺ signal occurs within a few minutes following fusion of the gametes (Jones et al., 1998), although in insects, where fertilization is dissociated from activation and where embryos can develop in the absence of a male genome, parthenogenesis, the presumed Ca²⁺ increase is induced by mechanical stimulation during transport through the female reproductive tract (Sartain and Wolfner, 2013). The advent of imaging methodologies allowed researchers to gain insights into the spatio-temporal features of Ca²⁺ responses during fertilization. Using the luminescent protein aequorin, it was first demonstrated that the single Ca²⁺ rise in fish and sea urchin eggs is explosive and propagates through the egg as a wave initiating from the point of sperm entry (Ridgway et al., 1977). Later studies using fluorescent probes demonstrated the same feature to characterize the first Ca²⁺ rise in mammals (Deguchi et al., 2000; Stricker, 1999). Nevertheless, in these species, the sperm-initiated Ca²⁺ responses continued at periodic intervals, also known as Ca²⁺ oscillations (Miyazaki et al., 1986), which occur every 10–40 min according to the species, and last for more than 4 h (Miyazaki and Ito, 2006; Wakai et al., 2011). The persistent oscillations are needed to support the events of egg activation, which necessitate different numbers of oscillations for their initiation, and whose completion requires more rises than for their initiation (Ducibella and Fissore, 2008). Eggs that age postovulation are an exception, as they might be activated by single Ca²⁺ rises (Whittingham and Siracusa, 1978). It is worth noting that completion of the first cell cycle in mammals demands in excess of 20 h, whereas in most other species this stage is completed in less than 120 min (Stricker, 1999).

The Ca^{2+} Toolkit

The fertilization signal depends on Ca^{2+} release from intracellular stores. To accumulate, release, restore and maintain Ca^{2+} levels both in the stores and in the cytoplasm, i.e., Ca^{2+} homeostasis, cells, including oocytes and eggs, use a set of complementary molecules collectively referred to as the Ca^{2+} toolkit (Fig. 2). The endoplasmic reticulum (ER) is the cell's main Ca^{2+} reservoir, and Ca^{2+} release from the ER underlies multiple cellular events in a wide array of cell types (reviewed in Berridge, 2009). Ca^{2+} release from the ER is mostly mediated by 1,4,5-inositol trisphosphate (IP_3) and its cognate receptor, IP_3R , which is the main Ca^{2+} release channel in nonmuscle cells. IP_3Rs function as tetramers and mammalian eggs predominantly express the type I isoform (Jellerette et al., 2000; Parrington et al., 1998). Technical limitations have thus far prevented the detection of IP_3 synthesis during fertilization in mammals, although such production has been detected during sea urchin and amphibian fertilization (Stith et al., 1993; Turner et al., 1984). Further, injection of IP_3 or of its analogues into mammalian eggs initiated Ca^{2+} oscillations (Miyazaki, 1988). Phospholipase C enzymes, PLCs (reviewed in Rebecchi and Pentyala, 2000), which are required for the hydrolysis of phosphatidylinositol-4,5-bisphosphate (PIP_2), have been detected in mammalian eggs at the transcript and/or protein levels (Dupont et al., 1996; Igarashi et al., 2007), although their contributions to Ca^{2+} oscillations are presently unknown, as specific inhibitors failed to disturb fertilization-associated oscillations. It has therefore been suggested that the PLC responsible for the oscillations is delivered by the sperm (see later). It is worthwhile noting however that one of the egg's PLC, $\text{PLC}\gamma$, is indispensable for Ca^{2+} release during sea urchin, ascidian, and *Xenopus* fertilization (reviewed in Runft et al., 2002).

The ER and IP_3R s undergo reorganization during oocyte maturation displaying a prominent cortical cluster distribution. This organization, together with the phosphorylation of IP_3R and accumulation of Ca^{2+} in the ER, enhance the function of IP_3R in preparation for fertilization (Ajduk et al., 2008; Wakai et al., 2011). IP_3R mediated Ca^{2+} release is required for the first Ca^{2+} wave and for the subsequent oscillations in the mouse and most likely in all mammals, as a functional blocking antibody against it prevented initiation of Ca^{2+} oscillations (Miyazaki et al., 1992) and egg activation (Xu et al., 1994); similar results were reported for other species (reviewed in Florman and Fissore, 2015). The IP_3R is particularly well suited to mediate the oscillations, as it is gated both by IP_3 and Ca^{2+} , where a high concentration of Ca^{2+} inhibits the channel (Iino, 1990). As oscillations persist, IP_3R undergoes a protracted degradation that depends on the same production of IP_3 that underlies the oscillations; this downregulation contributes to the slow down and eventual termination of the oscillations (Jellerette et al., 2000).

For oscillations to persist, Ca^{2+} levels must be returned to baseline after each rise and Ca^{2+} influx be promoted, as oscillations cease prematurely in conditions devoid of external Ca^{2+} (Igusa and Miyazaki, 1983). Cells use several molecules to maintain basal Ca^{2+} levels including the sarco-endoplasmic reticulum Ca^{2+} ATPases (SERCAs), which uptake Ca^{2+} into the ER, PM Ca^{2+} ATPases (PMCA), and $\text{Na}^+/\text{Ca}^{2+}$ exchangers, which extrude/exchange Ca^{2+} out of the cell (Berridge, 2002). These mechanisms are functional in mammalian eggs, as their pharmacological manipulation altered and/or terminated oscillations (reviewed in Wakai et al., 2011, p. 520; Miao and Williams, 2012). Cells also use a variety of PM channels to influx Ca^{2+} (Clapham, 2007, p. 499). Mouse eggs express voltage-gated Ca^{2+} (VGC) channels as well as components of the store-operated Ca^{2+} entry mechanism, although mice null for these channels are fertile (Bernhardt et al., 2017). Mammalian eggs also express members of the TRP family

Fig. 2 The fertilization Ca^{2+} toolkit. A series of molecules are required by oocytes and eggs to initiate and maintain Ca^{2+} oscillations and homeostasis. At fertilization, the sperm delivers a $\text{PLC}\zeta$, which hydrolyzes PIP_2 into IP_3 and diacylglycerol (DAG). IP_3 binds its receptor, IP_3R , causing Ca^{2+} release from the ER. Following Ca^{2+} release, part of the elevated free Ca^{2+} is removed to the extracellular media by the action of the PM Ca^{2+} pump PMCA and/or of a $\text{Na}^+/\text{Ca}^{2+}$ exchanger. The SERCA pump reuptakes part of the elevated free Ca^{2+} from the ooplasm into the ER stores, thereby refilling them. To maintain Ca^{2+} oscillations and refill the stores, eggs need Ca^{2+} influx from the extracellular milieu. To accomplish this, a variety of PM channels mediate Ca^{2+} influx. In mouse oocytes and eggs, TRP and/or Cav3.2 T-type channels are proposed to mediate the majority of this influx, although the PM channels that mediate Ca^{2+} influx during maturation and fertilization in other species remain to be fully identified.

of ion channels but their contributions to Ca^{2+} oscillations during fertilization remain undetermined, although TRPV3 is required for SrCl_2 influx (Carvacho et al., 2013), which in mouse eggs is used as a common parthenogenetic procedure, and TRPM7 is required for early embryo development (Jin et al., 2012). Therefore, mouse eggs possess a complete tool kit, although the role and specific molecules involved in the regulation of each of parameter of Ca^{2+} homeostasis remains to be elucidated.

Sperm-Specific PLC ζ

The long-lasting oscillations of mammalian fertilization require a mechanism(s) and/or molecule capable of remaining active for extended period of time. The demonstration that injection of soluble extracts from sea urchin and ascidian sperm, sperm factors (SF), into homologous eggs triggered activation events similar to those of fertilization (Dale, 1988) led to the hypothesis that a sperm component(s) could initiate the oscillations after diffusing into the ooplasm. In support of this notion, injection of mammalian SFs into eggs replicated the events of fertilization and induced oscillations (Swann, 1990). Analysis of the SFs revealed the active component(s) was a protein moiety of $\sim 40\text{--}100$ kDa MW that displayed PIP_2 hydrolyzing activity, which was highly sensitive to Ca^{2+} and therefore capable of operating at basal intracellular Ca^{2+} levels (reviewed in Swann and Lai, 2016). Studies later identified a novel sperm-specific PLC, PLCZeta1 or ζ , as the active component of mammalian SFs (Saunders et al., 2002). Consistent with this, PLC ζ was present in the active SF fractions, its removal abrogated the activity of the extracts, and injection of its cRNAs induced sperm-like oscillations (Kurokawa et al., 2005; Saunders et al., 2002). Injection of recombinant PLC ζ induced similar responses (Yoda et al., 2004). The localization of PLC ζ in the equatorial and/or postacrosomal region of the sperm head is consistent with its rapid transfer into the ooplasm after gamete fusion (Fujimoto et al., 2004; Yoon and Fissore, 2007). Finally, the structure of PLC ζ is similar to that of other PLCs, although it lacks several regulatory domains found in other PLCs including a pleckstrin homology domain, which renders it soluble (Saunders et al., 2002; reviewed in Nomikos et al., 2013, p. 80). Therefore, this novel sperm-specific PLC ζ is endowed with unique properties that makes it specially suited to initiate and maintain oscillations in eggs; it may also underlie egg activation in other vertebrates species such as certain fish and birds (Coward et al., 2011; Ito et al., 2011).

Infertility and Egg Activation

Intracytoplasmic Sperm Injection (ICSI)

The injection of sperm into the ooplasm bypassing fusion of the gametes, which is known as ICSI, was initially developed to study fertilization in mammals. It was later applied in the clinic to overcome male infertility, many cases of which until then had poor prognosis. It has had unprecedented success, and today nearly 50% of the live births reported by fertilization clinics are the result of this procedure (reviewed in Neri et al., 2014). The application of ICSI has now been extended to nearly all other mammals, where mostly results in efficient production of offspring. Remarkably, the success of this technique has served to prove the concept that a sperm component is responsible for egg activation and of initiation of the Ca^{2+} oscillations in mammals, as bypassing the interaction and fusion of the gametes' membrane does not affect egg activation and/or embryo development. Consistent with this, follow up studies found that ICSI initiated Ca^{2+} oscillations very similar to that of fertilization (Nakano et al., 1997). Therefore, ICSI has wide applications both in the clinic as well as in the laboratory.

Infertility and PLC ζ

Fertilization by ICSI offers advantages over conventional fertilization in mammals in that it is possible to know the time of sperm entry as well as achieve synchronous fertilization. Further, unlike in vitro fertilization, IVF, where a wide array of sperm defects, ranging from motility, to interaction and/or penetration of the zona pellucida and/or defects in fusion, can underlie the failure of fertilization, only a few sperm deficiencies can undermine fertilization by ICSI; these defects are mostly related to failure of release and/or function of the egg-activating stimulus. In agreement with this, only $\sim 3\%$ of ICSI cases fail fertilization, and for the most part they all display a uniform phenotype, which is failure of egg activation. This was the case with the unusually high numbers of fertilization failures following ICSI with globozoospermic sperm, which are missing the acrosome. Later studies showed that these sperm lack or have reduced levels of PLC ζ (Yoon and Fissore, 2007), and this defect is associated with loss of expression of a novel gene, Dpy19L2, which is required for the organization of the sperm's perinuclear theca, the site of PLC ζ localization (Escoffier et al., 2015). Other cases of fertilization failure or reduced rates of fertilization are associated with specific mutations within different domains of PLC ζ (Escoffier et al., 2016; Kashir et al., 2012). Therefore, analysis of cases of fertilization failure after ICSI combined with whole exome sequencing and mutational studies have yielded insights into the mechanism of mammalian fertilization, and this approach promises to aid in uncovering the mechanism(s) that regulate the function of PLC ζ both in the sperm and in the ooplasm, which are presently unknown.

Genetic Models

The ultimate demonstration that a molecule is required for fertilization and/or initiation of development is to examine how its elimination impacts the fertility of the individual or of its progeny. On occasions this approach fails, as elimination of a gene results

in embryonic lethality or, alternatively, in abrogation of spermatogenesis. Using the CRISPR-Cas technology, researchers generated mice devoid of PLC ζ and with normal spermatogenesis (Hachem et al., 2017). The analyses of these males showed PLC ζ null sperm are unable to mount normal Ca²⁺ oscillations, which compromises the progression of all events of egg activation, especially the blocks to polyspermy. Lastly, these males were subfertile but not sterile, as females paired with them produced smaller litters at greater intervals. These results raise important questions, such as are mice the exception in producing offspring without a normal activation stimulus? What are the effects on the offspring's behavior and life expectancy? Ultimately, these PLC ζ null males are a great tool to ascertain the role of Ca²⁺ and downstream molecules in egg activation and initiation of development. It is noteworthy that a knockout mouse line was recently generated for PAWP, a molecule also suggested to be involved in egg activation. Elimination of this protein had no consequences on fertility or spermatogenesis, suggesting that its function in fertility is dispensable (Satouh et al., 2015).

Outlook

Great progress has been made over the last 30 years in understanding the mechanisms of fertilization and egg activation. Some of these findings have been successfully translated into the clinic for the treatment of infertility. Nevertheless, some important questions remain. For example, what molecule(s) mediate(s) gamete fusion in mammals? Or, how necessary are Ca²⁺ oscillations for normal embryo development in vivo? What are the PM channel(s) that mediate Ca²⁺ influx? Answers to these questions will be the basis for the design of novel, non-hormonal methods of contraception, better egg activation procedures, and culture media for oocyte maturation and embryo development. Over the next decades we expect the progress to accelerate, aided by the ability to more easily edit the mammalian genome and advances in imaging technologies. These discoveries should assist in the treatment of infertility, production of animals with better productive and reproductive profiles and resistance to disease, and in the preservation of endangered species.

Acknowledgments

The authors would like to thank Changli He, Goli Ardestani, and previous members of the Fissore lab for their research contributions and helpful discussions that shaped part of this article. This work was supported in part by funds from the National Institute of Child Health and Human Development (HD051872) and NIFA to RAF. Due to space constraints, we apologize to those authors whose worthy contributions have not been mentioned.

Mammalian Gestational Strategies: Embryonic Diapause and Pseudopregnancy

Bruce D Murphy, Université de Montréal, St-Hyacinthe, QC, Canada

Introduction

The key to evolutionary success in any lifeform is its ability to successfully reproduce and pass its genetic information on to succeeding generations. It is for this reason that evolution has favored strategies that maximize reproductive success. One of these is viviparity, the capacity for the development of the embryo and the fetus to occur within the body of the mother. While not restricted to mammals, viviparity is a strategy that accounts for much of the evolutionary success of mammals (Bainbridge, 2014). Widespread adaptation of variation in reproductive anatomy, physiology, and behavior further accounts for the survival of diverse members of the Class *Mammalia*. Two of the strategies that have contributed to this success are pseudopregnancy and embryonic diapause, the latter also known as delayed implantation.

Pseudopregnancy

Pseudopregnancy, also known as pseudocyesis, can be defined as a condition that resembles pregnancy, but in the absence of a fetus incubating in the uterus. In nature, it will reduce the frequency of pregnancy for a species and is seemingly contrary to the concept that maximum reproduction assures evolutionary success. For this reason, in most species, it is a relatively rare phenomenon. In experimental contexts, pseudopregnancy can be readily induced, and these models have provided valuable insight into reproductive function, in particular to the understanding of signals to register presence of the embryo in the uterus. Examples from two orders of mammals, *Rodentia* and *Carnivora*, have been chosen to illustrate the physiology of pseudopregnancy.

Rodents

Laboratory species of rodents, including the mouse, rat, and hamster, ovulate spontaneously and undergo repeated 4-day estrous cycles if not bred. The luteal phase, that is, the life span of the corpus luteum, comprises metestrus and diestrus and is but 2 days in unbred animals. If the animals are mated during this time, the luteal phase is extended until placental steroid hormone secretion, primarily progesterone, takes over the support of pregnancy (Ben-Zimra et al., 2002). The key event in conversion of the short-lived corpus luteum of the cycle to the longer surviving corpus luteum of pregnancy is the initiation of daily peaks of prolactin secretion from the pituitary (Fig. 1). In the mouse and rat, these occur twice daily, while a single peak characterizes the hamster signal. If these animals are mated to an infertile male, the corpus luteum and thus a state of pseudopregnancy will persist for 7–10 days. Then the well-known uterine secretion of prostaglandin F₂ α , produced by the endometrium in the absence of the embryo, will induce luteal demise. When the embryo is present, the trophoblast in the developing placenta secretes a prolactin-like hormone, placental lactogen-1 α that takes the place of prolactin and maintains the corpus luteum (Soares, 2004). If not, there is rapid loss of the capacity to synthesize progesterone, and eventually, there is structural regression of the corpus luteum. The hormonal profiles that demonstrate the differences among the cycling, pseudopregnant, and pregnant rat are depicted in Fig. 1.

Carnivores

Pseudopregnancy occurs in both felids and canids, and the best-studied models are the domestic cat and dog. In both, the duration of the luteal phase differs between the pseudopregnant and pregnant animals. In the domestic cat, ovulation is induced by copulation, and the consequent pregnancy supported by the corpus luteum has a duration of approximately 65 days. Circulating progesterone in pregnant animals increases through the first 25 days following mating and then begins to decline. The support of gestation is supplemented from the placenta, but luteal progesterone is essential to prevent abortion (Verstegen et al., 1993). If the queen is mated with a sterile male, a condition of pseudopregnancy ensues with functional corpora lutea that begin to regress approximately 20 days later, and luteal regression is complete by 40 or so days (Jewgenow et al., 2012). Administration of dopamine agonists at 30 days after mating effectively reduces prolactin secretion in the pregnant female cat, with the consequence of reduced progesterone synthesis, and abortion within a few days (Eilts, 2002). This indicates that prolactin is the principal luteotropic signal and is therefore expected to be responsible for the maintenance of the corpus luteum of pseudopregnancy. The embryonic signal that prevents luteal regression in the pregnant animal has not been discovered (Bazer, 2015).

Pregnancy and pseudopregnancy in the domestic dog have been studied in more detail than in other carnivore species, and much of what we know is due to the pioneering work of Concannon (2011). In contrast to the cat, the dog ovulates spontaneously, and pseudopregnancy is a common condition. It is often accompanied by mammary development and behavioral changes that mimic pregnancy, and lactation can be induced (Gobello et al., 2001). As with the cat, the luteal dynamics and progesterone profiles differ between pregnancy and pseudopregnancy, but not in the same manner. In the dog, the corpus luteum is required for the duration of pregnancy, as ovariectomy at any stage results in abortion. During pseudopregnancy, the canine corpus luteum has lower

Fig. 1 Comparison of circulating profiles of the pituitary hormone, prolactin, and the ovarian hormone, progesterone, during cycling, unmated, pseudopregnant, and pregnant laboratory rats. Modified from Ben-Zimra, M., M. Koler, N. Melamed-Book, J. Arensburg, A. H. Payne, and J. Orly. (2002). Uterine and placental expression of steroidogenic genes during rodent pregnancy. *Molecular and Cellular Endocrinology* **187** (1–2), 223–231.

progesterone output relative to its pregnant counterpart (Concannon, 2011), but it can persist for weeks or more beyond the normal 60 or so day luteal phase in the pregnant animal (Kowalewski et al., 2015). The canine corpus luteum appears independent of gonadotropin influence for the first 25 days after ovulation, but for the remainder of gestation, the pituitary hormones, prolactin (PRL) and luteinizing hormone (LH), are required to maintain it (Concannon, 2011). Recent studies have shown that luteal expression of the genes for both LH and PRL receptors occurs in the pregnant bitch at parturition, but similar changes do not occur in the pseudopregnant animal, indicating different mechanisms of regulation between the two conditions (Pagnano Derussi et al., 2017). The hormonal patterns in canine pregnancy and pseudopregnancy are depicted in Fig. 2.

Evolutionary Significance of Pseudopregnancy

A tenet of evolution dictates that species survival depends on reproductive success, and the normal status of fertile females is pregnancy or lactation during the breeding season. Thus, it is unlikely in most species that pseudopregnancy is a common occurrence. In contrast, in wild canids, a condition known as cooperative breeding has been described, where only the dominant female of a group or pack whelps and pseudopregnancy is obligate in subordinate females (Asa and Valdespino, 1998). The expected evolutionary advantage is that lactating pseudopregnant members of a group can then participate in nursing and nurturing young, increasing their chances for survival.

Embryonic Diapause

Mammals of diverse phyletic provenance display another reproductive strategy, known as embryonic diapause or delayed implantation. This term describes the capacity of the embryo to undergo a reversible arrest, rather than proceed in the course of continual development that characterizes embryogenesis in most species (Fenelon et al., 2014). With very few exceptions, this arrest is visited on the embryo at the blastocyst stage of development (Fig. 3), and the proximal temporal regulation is imposed by the uterine environment. Embryonic diapause has been identified in over 130 mammalian species from 10 different mammalian orders. Diapause in mammals occurs in two forms, facultative diapause, where it occurs during pregnancy under certain conditions in

Fig. 2 Hormonal profiles of pregnancy and pseudopregnancy in the domestic dog during pregnancy and pseudopregnancy. Modified from Concannon, P. W. (2011). Reproductive cycles of the domestic bitch. *Animal Reproductive Science* **124** (3–4), 200–210.

some species, but not necessarily in all gestations (Table 1). The second form is known as obligate diapause, in that it is a component of every gestation in a species. The division is not absolute, as some marsupial species display a combination of the two types of diapause, where lactational delay is further extended by seasonal photoperiodic cues. The distribution, characteristics, and regulation of each of these two forms of diapause are discussed later. Although the range of external mechanisms and processes acting on the uterine environment during this time can differ significantly among species, many of the molecular controls of embryonic diapause appear to have been conserved (Fenelon et al., 2014).

Facultative Diapause

Facultative diapause, also known as lactational diapause, is common in species of rodents that experience a postpartum estrus. In this case, the female will mate soon after birth of its litter and then will be suckling one generation of young, while the next is developing in the uterus. The energetic stress of lactation results in arrest in the development of the embryonic generation at the blastocyst stage. In the mouse, the best-studied species with respect to lactational diapause, the embryo of 30–40 cells hatches from the zona pellucida on the fourth day after mating, followed by proliferation to approximately 130 cells over the following 72 h (Fig. 3) (Lopes et al., 2004). The blastocyst is then in a dormant state, incapable of implantation. A small number of cells in both the trophoblast and the inner cell mass of the dormant blastocyst undergo autophagy, and this autophagy is essential for recycling of nutrients to the remaining cells (Lee et al., 2011).

The ovary serves as the proximal regulator of embryonic diapause in the mouse and rat (Fenelon et al., 2014). When gestation is not interrupted by diapause, progesterone secreted by the corpus luteum is essential for the early development and preimplantation survival of the embryo. During the morning of the fourth day following mating, there is a brief peak in the secretion of estrogen from the ovary that induces implantation. The cellular provenance of this secretion remains unknown. It has been shown by serial blood sampling and by generations of experimentation that this brief estrogen surge is the indispensable signal, without which diapause ensues (Fenelon et al., 2014). The endocrine mechanism that induces and maintains diapause in the rat and mouse is the secretion of prolactin associated with lactation, which then prevents the surge of estrogen that induces implantation (Renfree, 2015). The role of estrogen appears to be multiple and includes direct effects on both the uterus and the embryo. The former includes large-scale changes in gene expression by up- or downregulation of hundreds of genes (Lopes et al., 2004). Among the first to be identified by targeted deletion was leukemia inhibitory factor (*Lif*), followed by prostaglandin synthesis-2 (*Ptgs2*) (Lee et al., 2007). Noninclusive lists of uterine genes essential to implantation in the mouse can be found in reviews by Cha and Dey (2015) and Lee et al. (2007). The estrogen episode has the effect of awakening the dormant embryo, either directly or through uterine

Fig. 3 Diapause occurs at the blastocyst stage of development in species where it is present. In the mouse, diapause follows hatching of the embryo from the zona pellucida 4 days after mating. In the mink, the blastocyst forms in the oviduct at 6 days after induced ovulation. In the wallaby, the unilaminar (no inner cell mass) blastocyst forms at 6 days after ovulation.

Table 1 Comparison of the characteristics of the two types of diapause, facultative or lactational and obligate

Facultative diapause	Obligate diapause
Induced by lactational or other metabolic stress	Present in every gestation of a species
Usually brief in rodents	Most commonly regulated by seasonal changes in photoperiod
Months of duration in marsupials	Duration of months in most species
Induced by prolactin from the pituitary	Common in Ursid and Mustelid carnivores where prolactin terminates diapause.
	Also found in the Roe deer and armadillos.

intermediates. The rapid effects include the formation of multivesicular bodies in the trophoblast cells and removal of accumulated autophagosomes (Lee et al., 2011), along with a burst of cell proliferation and differentiation of the trophoblast to acquire the invasive properties required for implantation (Bedzhov et al., 2014).

In addition to rodents, more than 35 marsupial species across five orders display lactationally induced diapause (Fenelon et al., 2014). The best-studied species is the tammar wallaby (*Macropus eugenii*), where the joey is born and makes its way to the mammary gland in the maternal pouch. Parturition is accompanied by postpartum estrus, and fertilization results in a new embryo that is soon arrested at the blastocyst stage, approximately 80 cells (Fig. 3). This blastocyst differs from the Eutherian model in that it is surrounded by a shell coat and is unilaminar, that is, there is no defined inner cell mass (Fenelon et al., 2014).

The endocrine events associated with lactation are the key regulators of marsupial facultative diapause, as departure of the joey from the pouch results in reactivation of the dormant embryo. In the tammar wallaby, the first changes in the embryo can be seen after 4 days. This is followed by embryo expansion some 4 days later and attachment to the endometrium after 18 days (Fenelon et al., 2014). During diapause, the corpus luteum is in an immature state, with only a basal level of secretion of the progesterone signal that is essential for the termination of diapause. Removal of the pituitary or blockade of prolactin secretion by dopamine

agonists results in increased progesterone secretion within 5 days (Renfree, 2015). While less is known about the uterine regulation of diapause in this species, a recent study has implicated epidermal growth factors as a conserved signal for termination of diapause (Fenelon et al., 2017b).

Obligate Diapause

The occurrence of a developmental arrest can be found in every gestation of a number of species, as diverse as the roe deer and the armadillo. Obligate diapause has been best studied in carnivores, where it can be found in more than 50 species in five orders (Fenelon et al., 2017a). The uncoupling of mating and parturition allows for mating during a favorable season, usually spring or fall, and parturition at a time optimal for neonate survival, usually spring. This gamut includes bears, wolverines, and aquatic species. The embryos of obligate diapause are uniformly in the blastocyst stage of development, but the number of cells present in the embryo usually far exceeds the complement found in rodent facultative diapause (Fig. 3) (Lopes et al., 2004). In the roe deer (*Capreolus capreolus*), for example, the blastocyst can be as large as 3 mm in diameter with more than 500 cells, while it is 1 mm in the nine-banded armadillo (*Dasypus novemcinctus*), with approximately 600 cells (Lopes et al., 2004).

The species that have been more extensively studied include the American mink (*Neovison vison*), the Western spotted skunk (*Spilogale gracilis*), and the European badger (*Meles meles*). In the former two of these species, the principal environmental regulator of obligate diapause has been definitively shown to be the seasonal change in photoperiod with increasing daylength, after the vernal equinox. This regulation is mediated through pineal secretion of melatonin (Fenelon et al., 2017a). The situation is opposite in seals, where implantation occurs during times of decreasing photoperiod (Atkinson, 1997). Diapause occurs in bears and its termination by implantation happens near the winter solstice, while the animals are in hibernation. There exists little information about regulation of diapause in these species, most likely because they are not a tractable model for study.

The photoperiodic effects are mediated through the hypothalamus–pituitary system (Fenelon et al., 2017a). In contrast to the facultative model of diapause, where prolactin is inhibitory to implantation, in the mustelid carnivores, prolactin plays a stimulatory role. In the members of the mustelid family that have been studied, the corpus luteum that develops following ovulation is small and actually regresses during the period of diapause (Mead, 1993). Prolactin is the essential signal for termination of diapause in that it induces massive increases in the secretion of progesterone and is the sole factor required for reactivation of the corpus luteum and consequent implantation (Fenelon et al., 2017a). The abundance of the prolactin receptor transcript in the mink corpus luteum is low during diapause and increases rapidly during reactivation. A concomitant increase in the expression of key steroidogenic enzymes also occurs. Although the embryo of the mink remains in diapause for around 1–2 weeks and the embryo of the spotted skunk remains in diapause for 6 months, the dynamics of luteal function are similar (Mead, 1993). In many carnivores, the progesterone profiles during diapause and reactivation, as determined by noninvasive evaluation of feces or urine, or indirectly by monitoring of body temperature, have been found to follow the pattern of a period of low progesterone secretion, followed by large increases associated with implantation (Fenelon et al., 2017a).

The proximal site for control of obligate diapause is the uterus, and two possible regulatory regimes can be envisioned. In the first, the uterine environment actively inhibits the development of the embryo beyond the blastocyst stage by secretion of one or more factors that interfere with the progression of embryogenesis. The second possibility is that the uterine environment lacks the appropriate constituents to support continued development. Available information support the latter hypothesis, in that reciprocal transplants of arrested blastocysts from a diapause species to a closely related species that does not display diapause results in reactivation of the embryo and implantation (Chang, 1968). Further, incubation of arrested blastocysts with immortalized uterine stroma can result in reactivation of development (Fenelon et al., 2017a).

Studies of uterine candidate genes associated with termination of obligate diapause showed that prostaglandin synthesis, and particularly, prostaglandins of the E-series were expressed by the uterus at the time of implantation, along with leukemia inhibitory factor (LIF) as an essential factor for rodent implantation (Fenelon et al., 2017a). Global gene analysis revealed that there are multiple genes that are upregulated or newly transcribed associated with activation of the embryo (Lefevre et al., 2011a). Gene ontology analysis focused on secretory factors and validation studies identified growth factors, as well as factors associated with the initiation and maintenance of the cell cycle (Lefevre et al., 2011a). It was discovered that a cluster of genes that regulate the synthesis and metabolism of the polyamines were likewise upregulated and associated with embryo activation (Lefevre et al., 2011b). In subsequent studies, it was shown that the polyamine, putrescine, can induce activation of the embryo from a diapause state and support its further development in vitro (Fenelon et al., 2017a). Polyamines play multiple roles in cell function, among these are the stimulation of gene expression, cell proliferation and tissue growth (Lefevre et al., 2011c). These are effects consistent with the reactivation of the dormant blastocyst. These findings argue that the basis of embryonic arrest is the absence of stimulation by polyamines and other uterine factors.

Evolution of Diapause

The phenomenon of embryo arrest can be found in both the animal and plant kingdoms, and as noted above, a wide range of mammals either display or can be induced to display this characteristic. Sandell (Sandell, 1990) hypothesized that diapause evolved independently multiple times, in both its facultative and obligate manifestations. This conclusion is based on the presence or

absence of diapause in congeneric species such as the ermine (*Mustela erminea*) and the least weasel (*Mustela nivalis*), a species that displays no diapause. In the spotted skunk, the western species (*Spilogale gracilis*) displays obligate diapause and its eastern counterpart, (*Spilogale putorius*), does not (Mead, 1993). The theory of convergent evolution of diapause is further supported by its manifestation in a wide variety of species, including armadillos, at least one mole, three species of bats, and an ungulate. These diverse species display considerable divergence in placentation, postimplantation embryogenesis, and other reproductive traits. As can be seen in the model species, the diversity of regulatory mechanisms further argues for independent evolution of diapause. Prolactin maintains diapause (marsupials), terminates diapause (mustelids), or has no effect (rodents). The ovaries are essential for implantation in the model species, but, remarkably, in the nine-banded armadillo, embryo reactivation and implantation are induced by ovariectomy (Buchanan et al., 1956).

Arguing for a single evolutionary event in mammals is the conservation of multiple mechanisms. For example, the transcriptional repressors coded by the muscle segment homeobox genes (MSX) are expressed in uterine stroma during diapause and are rapidly downregulated when the arrested blastocyst is reactivated (Cha et al., 2013). MSX1 is present in the mouse uterus during facultative delay, and in its absence, diapause and implantation do not occur. MSX1 is present in the stroma of the mink uterus during diapause, and MSX2 can be found in the uterus of the tammar wallaby (Cha et al., 2013). Likewise, the expression of epidermal growth factor (EGF) and heparin-binding EGF (HBEGF) and their receptors in the uterus are upregulated at the termination of diapause and reactivation of the embryo in both the wallaby and the mink (Fenelon et al., 2017a). Polyamine deprivation in vivo induces a state of diapause in both the mouse (Fenelon and Murphy, 2017) and the mink (Fenelon et al., 2017a). Facultative diapause, by its very nature, is inducible by metabolic stress and can be present in both rodents and marsupials. But can diapause be induced in species where it appears never to occur during normal pregnancy? In a single study, Ptak et al. (Ptak et al., 2012) induced diapause in sheep, a nondiapause species, by transfer of the embryos to the uterus of a mouse where the diapause condition had been experimentally induced by ovariectomy and hormone treatment. When the sheep embryos were transplanted back to the uteri of the ewes, live lambs were born. Thus, the hypothesis of a single evolutionary event remains viable and is perhaps the best explanation for the occurrence of diapause in mammals.

Pregnancy Recognition Signals With an Emphasis on Ruminants

Maternal Recognition of Pregnancy

In placental mammals, the ovarian follicular structure remaining after ovulation of an oocyte in the mature female transforms into a structure called the corpus luteum (CL), whose major role is to produce the hormone of pregnancy, progesterone. If the oocyte does not become fertilized, the CL (or CLs in the case of species that ovulate more than a single egg) regresses, and a new ovarian cycle begins. However, if fertilization is successful and if the pregnancy is to prosper, with some exceptions, such as in the bitch where the length of the luteal phase of the estrous cycle approximates the length of gestation, the functional lifespan of the CL must be increased (Bazer, 2015). This extension is necessary to provide continued production of progesterone, a steroid hormone whose action on the mucosal surface of the uterus (the endometrium) converts it to a state that allows the conceptus to attach to the uterine wall and subsequently to develop until it can survive outside the uterine environment. Although an ovarian supply of progesterone is not necessarily essential throughout pregnancy, because, the placenta itself can often be an alternative and sometimes necessary source of the steroid, it is invariably crucial in the early stages. In those few species of eutherian mammal where maternal recognition of pregnancy has been studied, it is the extra-embryonic trophoblast tissue that is the major player preventing luteal regression and ensuring conceptus survival, although the means by which this is achieved varies markedly across taxa and is understood in detail for only a few. Here we describe the discovery, function, and evolution of interferon-tau (IFNT), the anti-luteolytic factor responsible for luteal rescue in the Ruminantia, a sub-order within the Artiodactyla that includes the families Bovidae, Cervidae, Antilocapridae, Giraffidae (Leaman and Roberts, 1992), and, based on their close phylogenetic position to the Bovidae, the Moschidae (musk deer). As far as is known, no species outside this taxonomic grouping possesses a family of genes orthologous to the *IFNT*. Moreover, it is unclear whether any other mammalian grouping exploits IFN signaling pathways to accomplish CL rescue, although the conceptuses of some species, most notably the pig, do release both a Type I IFN (interferon-delta; IFND) and a Type II IFN (interferon-gamma; IFNG). However, more is probably known about maternal recognition of pregnancy in the ruminants than in any other mammal, including the human (and other primates) and laboratory animal species, such as the mouse, rat, and guinea pig.

It is well established that luteal regression in cattle and sheep, and most likely in all sub-primate species, is caused by the release of prostaglandin F₂-alpha (PGF) by the uterine endometrium towards the end of the ovarian cycle. In ruminants, at least, it is generally believed that it is the pulsatile pattern of PGF discharge rather than the threshold concentration achieved that is most critical in causing CL demise. In an animal that is pregnant, the conceptus rescues a CL hovering on the point of regression by dampening the production and/or pulsatile nature of PGF output from the endometrium. By the late 1970s it was clear that the active factor was proteinaceous in nature and produced by the conceptus for a few days during the short period in which it elongates from a sphere to a thread-like form that occupies both uterine horns (Roberts et al., 1992). Extracts of these tissues were sufficient to extend the lifespan of an ovine CL from a few days to several weeks although this state of pseudopregnancy never corresponded to the length of a normal gestation, which is approximately 140 days. Clearly other factors are required to reinforce the initial extension brought about by the trophoblast extracts, and these remain uncharacterized to this day.

The history of events that led to the characterization of the protein we now know as IFNT has been extensively reviewed (Roberts et al., 1992; Bazer and Thatcher, 2017; Ealy and Woodridge, 2017). Although Martal and colleagues partially purified a low Mr. protein (trophoblastin) from extracts of sheep conceptuses prepared at the time the conceptuses were releasing the anti-luteolytic factor, it was not fully characterized; nor was it purified in sufficient quantities to determine whether it was capable of extending luteal lifespan when injected into the uterine lumen of a non-pregnant ewe. A group of scientists at the University of Florida took a slightly different approach (Reviewed by Roberts et al., 1992). Reasoning that the protein must be secreted in relatively large quantities, they flushed d 14–17 ovine conceptuses from the uterine tract and cultured them for up to 48 h under serum free conditions in presence of radioactive amino acids. Through use of two-dimensional gel electrophoresis they noted a dominant secretory product consisting of 3–4 polypeptides of slightly acidic pI and Mr. about 18,000. Parallel studies performed on bovine conceptuses revealed a similar group of polypeptides of slightly higher Mr., which we now know to be glycosylated. The ovine product proved relatively simple to purify in sufficient amounts to demonstrate it could extend the estrous cycle of non-pregnant ewes. Antisera were also produced, which later allowed a bacteriophage cDNA expression library prepared from ovine conceptus mRNA to be screened and cDNAs to be cloned and sequenced. The inferred amino acid sequences provided a totally surprising result. The antiluteolytic factor, until then named variously as protein-X, ovine trophoblast protein 1 (oTP1) and trophoblastin, was clearly a Type I interferon (IFN), later officially called ovine IFNT-tau (ovIFNT). This IFN was structurally similar to, although clearly distinct from, interferon-alpha (IFNA) and interferon-beta (IFNB) and most resembled members of a lesser known family of Type I IFN, now named IFN-omega (IFNW). Two other groups subsequently confirmed the co-identity of trophoblastin and oTP1 and their close similarity to Type I IFN by molecular cloning techniques (Reviewed by Bazer and Thatcher, 2017). A structurally similar bovine IFN (boIFNT) was similarly identified after cloning its transcript from a bovine conceptus cDNA library.

The Anti-Luteolytic Action of IFNT

The cloning of the cDNAs for ovIFNT and boIFNT permitted the recombinant proteins to be produced in relatively unrestricted amounts in *E. coli* and yeast, and to be tested extensively in animals. However, even with the ready availability of the active proteins, it is still not completely clear how IFNT controls PGF production and release in order to protect the CL. What is apparent is that IFNT mainly acts locally, i.e. in a paracrine manner, on the endometrial epithelium to alter the expression of a wide array of genes, including the down-regulation of the gene for the oxytocin receptor (OXTR) (Reviewed by Hansen et al., 2017). The latter is usually up-regulated towards the end of the ovarian cycle in response to rising levels of estrogen. Evidence in sheep but not in cattle (Hansen et al., 2017) is consistent with the idea that towards the end of the second week of pregnancy IFNT inhibits transcription of *ESR1*, the gene encoding ESR1 (estrogen receptor 1), thereby preventing the estrogen-induced rise in OXTR. In absence of IFNT, oxytocin from either the pituitary or the CL binds to the uterine OXTR to initiate the release of small pulses of PGF into uterine venous blood. PGF then moves from the uterine vein to the ovarian artery by a countercurrent mechanism and triggers the release of additional amounts of oxytocin from the CL, which in turn stimulates further pulses of PGF by the uterine endometrium, thereby creating a positive feedback loop and ultimately causing luteolysis. IFNT may also decrease PGF production by down-regulating other key genes, including *PTGS2*, whose translation product catalyzes a rate limiting step in prostaglandin synthesis (Chen et al., 2006).

Like other Type I IFN, IFNT is a potent cytokine acting through the Type I IFN receptor, a complex of two subunits (IFNAR1 and IFNAR2), abundant on the uterine epithelium of the ewe. As with IFNA and IFNB, it directly regulates large numbers of what are often collectively called interferon-stimulated genes (ISGs), many of which are protective against virus pathogens (Chen et al., 2006). The fact that some IFNT appears to escape the pregnant uterus and enter the maternal blood stream suggests that it may act, not just locally, but in a far more systemic, endocrine manner, whose reach can be traced by following the induction of ISGs outside the immediate confines of the reproductive tract (Hansen et al., 2018). Indeed, one target is the ovary (Chen et al., 2006) where IFNT may induce luteal resistance to PGF (Reviewed by Hansen et al., 2017). The temporal induction of ISGs, especially ones that are secreted, may also provide an opportunity to test whether an animal is pregnant long before other tests are effective. Such tests, although not fully developed for commercial use, could be of particular value in the dairy and meat industries and also in zoos and conservation programs provided that they become reliable and not flawed by an abundance of false positives.

In summary, IFNT is released by the trophectoderm of the elongating conceptus before it attaches firmly to the uterine wall and is a crucial factor in the phenomenon of maternal recognition of pregnancy in ruminants by protecting the CL from PGF-induced destruction. It appears to accomplish this action in a number of ways: in an exocrine fashion by attenuating the release of luteolytic pulses of PGF from the uterine endometrium through control of OXTR concentrations, by down-regulating expression of endometrial *PTGS2* and other enzymes associated with PGF biosynthesis, and by a little understood, endocrine effects outside the uterine endometrium CL in ovary.

Expression of IFNT During Conceptus Development and Transcriptional Control of the IFNT Gene

Ovine (ov)IFNT production takes place largely between d 13–21 of pregnancy, with the peak at d 15, when a single cultured conceptus, which can be several cm in length, can produce as much as 0.5 mg of IFNT in 24 h (Roberts et al., 1992). These amounts are huge compared to any other known system known to generate a type I IFN, including virus-exposed leukocytes, especially as the K_d for the IFN receptor is in the region of 10^{-11} M (Reviewed by Hansen et al., 2017). These observations lend further credence to the premise that IFNT may need to target sites outside the reproductive tract as well as the uterine epithelium. A high rate of production is probably also important to trigger responses around the critical d 13 stage of development when the CL is on the point of regressing and when the tiny conceptus must exert an influence on both uterine horns if the pregnancy is to be maintained.

Although IFNT mRNA can be readily detected in ovine and bovine blastocysts, peak transcriptional activity is reached when the blastocysts have expanded and are just about to elongate, i.e. at about d 13 in the sheep, and ends during the period when the trophoblast forms a firm attachment with the uterine epithelium (Reviewed by Roberts et al., 1992). At all stages of development IFNT expression is confined strictly to the trophectoderm and silent in the inner cell mass and extraembryonic endoderm (Farin et al., 1989). In all these events relating to protein production and gene expression, similar outcomes are observed in cattle as in sheep, except events are delayed by two to three days. Expression in other ruminants can be inferred to be matched to the same elongation phase of development.

As discussed later, one feature that sets IFNT apart from other Type I IFN is their constitutive expression in trophectoderm and nowhere else, plus their lack of viral inducibility. There are no conserved viral response elements upstream of their transcription start sites. Instead, expression appears to be governed primarily by two regions (Leaman et al., 1994). One is a distal A/T rich element situated approximately –358 to –322 bp from the transcription start site, which has not been studied in detail. The second, more dominant one, is in a more proximal region (–91 to –69). Both of these regions form strong associations with nuclear proteins in electrophoretic mobility shift assays performed with extracts prepared from elongating ovine and bovine trophoblast. These complexes disappear as the IFNT become downregulated. Moreover, the removal of these enhancer regions, especially the proximal one, significantly reduces promoter activity.

Ezashi et al., used four tandem copies of the –91 to –69 region of the IFNT promoter as a 'bait' (or target) in a yeast single-hybrid system to screen for putative transcriptional regulators represented in a cDNA library prepared from day 13 elongating ovine conceptuses (Reviewed by Ezashi and Imakawa, 2017). The transcription factor ETS2 bound this bait sequence, which happens to contain a close-to-consensus ETS2 binding site with a central C/AGGAA/T core motif. The ETS2-binding motif is part of what appears to be a more complex enhancer with an adjacent AP1-binding site. Additionally, ETS2 is activated by the RAS/mitogen

Fig. 1 A speculative model for *IFNT* transcriptional control in trophoblast during the stage of conceptus elongation. Transcriptional regulators ETS2, AP1, and DLX3 interact with the *IFNT* 5' UTR proximal region. Growth factors released from maternal endometrium activate MAP kinase and PKA signaling pathways and increase *IFNT* transcription through induction and/or activation of transcription factors and coactivators that associate with the ETS2-enhancer region. Modified from Ezashi, T., Imakawa, K. (2017). Transcriptional control of IFNT expression. *Reproduction* **154**, F1–F11.

activated protein (MAP) kinase pathway and protein kinase A (PKA) pathway through the coactivator CREBBP, making it responsive to external factors present in the maternal uterine environment, such as the cytokine CSF1, that operate through RAS-GTP coupled receptors (Fig. 1) (Ezashi and Roberts, 2004). Finally, a series of additional transcription factors that, like DLX3, have been implicated in the emergence and maturation of the trophoblast lineage may operate in combination with ETS2 and AP1 to synchronize the remarkably rapid up-regulation and almost equally fast down-regulation of *IFNT* in the trophoblast, events that occur over the course of only about a week (Reviewed by Ezashi and Imakawa, 2017). These interactions are summarized in Fig. 1.

What Distinguishes IFNT From Other Type I IFN?

In the previous section we described some of the unique features of the IFNT, namely the lack of viral response elements within their proximal 5' UTR regions and their constitutive and localized expression to trophoblast. Despite these unusual attributes, the biological activities of IFNT are not very different from those of other type I IFN. For example, they bind to the same Type I IFNAR1/IFNAR2 receptor system with high affinity, and, as a consequence, are powerful antiviral, anti-proliferative, and immunomodulatory agents (Reviewed by Bazer and Thatcher, 2017; Roberts et al., 1992). These actions appear to be mediated primarily by the same JAK-STAT1/STAT2-IRF1 signal transduction pathway utilized by the other Type I IFN (Stewart et al., 2002) and cause a similar up-regulation of a common set of interferon-responsive genes (IRGs) (Hansen et al., 2017). Indeed, IFNA, when injected into the uteri of non-pregnant cattle, is also able to induce an extension of the estrous cycle comparable in length to that achieved with boIFNT (Roberts et al., 1992). Finally the six-amino acid (aa) sequence at the carboxyl tail of the 172 IFNT, which distinguishes these proteins from the 166 aa IFNA, appears to have little significance in terms of biological potency (Ealy et al., 1998).

One conclusion that might be drawn from these data is that the exceptionality of the IFNTs does not reside in their biological and structural properties. Instead, their uniqueness relates to where they are expressed, the timing of their expression, and the quantities in which they are produced. These are features most likely conferred by powerful selection for changes in nucleotide sequences outside the open reading frames of their genes.

However, over the course of the past 20 years there have been a series of reports that ovIFNT, in particular, is anti-inflammatory and somehow less toxic than other type I IFN. It has been claimed for example that this reagent might have therapeutic value in treating autoimmune diseases, such as multiple sclerosis, obesity, and even HIV AIDS (Bazer and Thatcher, 2017). To the authors' knowledge none of these claims have been vindicated in clinical trials. Nor has there been extensive laboratory follow-up on the initial reports.

Evolution of the IFNT

It quickly became apparent from the nucleotide sequences of transcripts and cloned genes, as well as from genomic Southern blotting, that cattle, sheep, and most likely other pecoran ruminants possessed more than a single IFNT gene

Fig. 2 Phylogenetic Tree of the Bovine Type I IFN. The evolutionary history of bovine Type I *IFN* was inferred by using the Neighbor-Joining (NJ) method. The tree was rooted to *IFN-kappa* (*IFNK*) and calculations were based on uniform rates of change for all sites.

(Leaman and Roberts, 1992). How many such genes are actually present in a particular genome remains unclear, however, because recently spawned tandem repeats occurring via either gene duplication events or by gene conversion are difficult to distinguish. Additionally, numerous sequence variants have been detected by cloning RNA from individual conceptuses. For example 26 such sequences have been cloned from cattle conceptuses (Ealy and Woolridge, 2017). Some of these transcripts may represent allelic variants, others novel genes. There are also indications that different breeds within a species and even individual animals within a breed may vary in the number and nature of *IFNT* they possess. The sequenced genome of a single Hereford bull revealed only three *IFNT* (Fig. 2), but none of these had exact sequence matches to the transcript sequences, including the two commonest, present in data bases (Walker and Roberts, 2009). Fig. 2 also illustrates the extraordinary recent expansion of the IFNW family in cattle, and defines a previously unknown family, the IFNX, whose function is unknown but which emerged well before the *IFNT* and *IFNW*.

Despite this uncertainty about gene number, calculations based on nucleotide substitution rates indicate that the *IFNT* and their nearest relatives, the *IFNW*, which also consist of a 195 aa codon open reading frame, diverged approximately 35 million years ago in the lineage leading to present day cattle, deer, giraffes, and their relatives. As a consequence, the *IFNT* do not occur outside of the ruminant, even-toed ungulates. The evolution of the *IFNT* from a progenitor *IFNW*, which was most likely involved in responses to pathogens, to a non-virally inducible placental hormone necessary for pregnancy recognition must have coincided with the acquisition of powerful trophoblast-specific enhancer elements in its genes. This unique mechanism for trophoblast signaling appears to have evolved, therefore, in parallel with the distinctive, evolutionarily advanced, non-invasive, synepitheliochorial placentation that characterizes pecoran ruminant species.

Introduction and Historical Perspectives

The highly-coordinated series of events leading to the establishment of pregnancy are largely orchestrated by the embryo. The presence of a developing embryo ensures adequate progesterone synthesis from the corpus luteum (CL) initially which primes the maternal reproductive tract to both transport and receive the implanting embryo. Additionally, the embryo produces signals that directly promote uterine receptivity. In primates, the principal embryonic signal driving these central processes is Chorionic Gonadotropin (CG).

Our understanding of CG's functional role as a gonadotropin began long before the isolation, purification and characterization of this secreted hormone ([Bahl, 1969](#)). Placental tissue, a primary source of human CG (hCG) production, was described to stimulate genital tract growth and ovulation in rodents as early as 1910 ([Cole, 2010](#)). In a landmark discovery, Ascheim and Zondek developed the first clinical pregnancy test utilizing this functional role of CG ([Ascheim and Zondek, 1928](#)). Treatment of mice with urine from pregnant women induced ovarian follicular development with ovulation resulting in the presence of macroscopically enlarged ovaries with hemorrhages. The name Chorionic Gonadotropin was derived from the latin word for its source of origin, *chordata* or afterbirth, and its functional role stimulating gonads, or gonadotropin ([Cole, 2010](#)). CG is unique to humans and anthropoid primates, and although an equine CG exists, this chapter will focus on the role of CG in human and non-human primate reproduction. Since its discovery, CG has been determined to drive key physiologic functions during the establishment of pregnancy and, more recently, its potentially significant clinical utility in Reproductive Medicine has been under investigation.

Sources, Structure and Isoforms

The placenta and its embryonic derivatives, specifically trophoblast cells, represent the primary source of hCG, although 8-cell stage embryos have been described to produce hCG prior to blastocyst development ([Banerjee and Fazleabas, 2010](#); [Cunningham et al.,](#)

Table 1 hCG isoforms: source of production, structural differences and global function (adapted from Choi and Smitz, 2014; Cole, 2010)

<i>Isoform</i>	<i>Predominant Source</i>	<i>Structural Differences from hCG</i>	<i>Global functions</i>
hcG	Fused and differentiated syncytiotrophoblast cells	N/A	Lutotropic and antiluteolytic actions for progesterone secretion Endometrial epithelial cell secretory function Endometrial stromal cell survival Myometrial growth and relaxation during pregnancy Angiogenesis and recruitment of uNK cells for uterine vascular remodeling Differentiation of cytotrophoblast cells Testicular production of testosterone in the male fetus Promotes growth and invasion of cytotrophoblast cells for embryo implantation
H-hCG	Extravillous cytotrophoblast cells and choriocarcinoma cells	Longer, more complex oligosaccharide side chains	Promotes cancer growth and invasiveness
Free β -hCG	Advanced nontrophoblastic malignancies	Hyperglycosylated free β -subunit and lacks α -subunit	Mimics LH function to promote ovarian follicle development, ovulation and luteinization
Pituitary hCG	Anterior pituitary gonadotrophic cells	Sulfated rather than sialylated oligosaccharides	

2013). CG is a member of a family of hetero-dimeric glycoprotein hormones comprised of luteinizing hormone (LH), follicle stimulating hormone (FSH), and thyroid stimulating hormone (TSH). The structure of these glycoprotein hormones consists of an identical α subunit, and they differ largely based on their β subunits (Srisuparp et al., 2001). The shared α subunit is encoded by a single gene *CGA*, which produces a 92-amino acid residue glycoprotein with two N-linked oligosaccharides. Within the aforementioned group of glycoprotein hormones, CG and LH contain the highest degree of homology, and it is likely that CG, found only in equine and primate species, is an evolutionary derivative of LH present in all species (Bulun, 2011; Choi and Smitz, 2014). Genes for the CG and LH β subunits are found within a cluster of seven similar sequences, where four encode the CG β subunit (*CGB*, *CGB5*, *CGB7*, and *CGB8*), one encodes the LH β subunit (*LHB*), and the remaining two are pseudogenes (*CGB1*, *CGB2*). The CG β subunit consists of 145-amino acid residues with two N-glycosylation and four O-glycosylation sites, while LH undergoes cleavage resulting in a 121-amino acid sequence. The presence of multiple β subunit genes, enhanced promoter expression patterns and post-translational modifications favor increased levels and stability of CG in circulation. Overall, these evolutionarily developed features ensure CG is rapidly induced and maintained during the establishment of pregnancy.

Four well-characterized isoforms of hCG have been described: (1) hCG, (2) hyperglycosylated hCG (h-hCG), (3) free β -hCG, and (4) pituitary hCG (Choi and Smitz, 2014). These hCG isoforms differ in their biochemical and physiologic properties along with their source of synthesis (Table 1). hCG represents the predominant isoform during pregnancy and is produced by fused and differentiated syncytiotrophoblast cells of the developing chorionic villi of the placenta (Cole, 2010). Syncytiotrophoblast cells are placental epithelial cells in direct communication with the maternal endometrial vasculature at the maternal-fetal interface. hCG is the most well-characterized of hCG isoforms and coordinates traditional functions important for promoting CL secretion of steroid hormones to support the establishment of pregnancy while preventing its regression. These mechanisms along with embryonic and additional maternal responses to hCG will be further described in Section IV. H-hCG, as its name implies, contains longer, more complex oligosaccharide side chains as compared to hCG. H-hCG is produced by root or extravillous cytotrophoblast cells. Its expression peaks during the first trimester, exceeding that of hCG, and subsequently declines during the remainder of pregnancy. As a result of the additional sugar moieties, typical protein folding is altered exposing additional receptor binding regions, including the TGF β receptor, and functional roles (Cole, 2010). Functions of h-hCG are primarily autocrine on cytotrophoblast cells, promoting growth and invasion while preventing apoptosis, which is critical during implantation and placentation. However, tight regulation of h-hCG expression is necessary to prevent pathological invasiveness. For example, choriocarcinoma cells secrete high levels of h-hCG contributing to their malignant potential. Free β -hCG are hyperglycosylated hCG β -subunits, lacking α subunits. While found at low levels during pregnancy, elevations of free β -hCG are present in the setting of advanced stage nontrophoblastic malignancies (Cole and Butler, 2008). Without an α subunit, free β -hCG does not activate canonical hCG signaling through the LH/CG receptor but likely promotes cancer development and invasiveness through non-canonical pathways described for h-hCG (Cole, 2009). Lastly, pituitary hCG is secreted by anterior pituitary gonadotrophic cells and consists of sulfated rather than sialylated oligosaccharides, resulting in its much shorter half-life than hCG (Cole, 2010). Pituitary hCG secretion occurs in a menstrual cycle-dependent fashion mirroring LH in both pattern and function, promoting ovarian follicle development, ovulation and luteinization with progesterone secretion.

LH/CG Receptor Structure, Localization and its Downstream Signaling

Both LH and hCG exert their canonical signaling through a shared receptor, the LH/CG receptor (LHCGR). The LHCGR is a 675-amino acid member of the glycoprotein hormone receptor subfamily within the superfamily of G-protein-coupled receptor

(GPCR)/seven-transmembrane domain receptors superfamily (McFarland et al., 1989). TSH and FSH receptors are classified within the same subfamily, consistent with the structural similarities of these glycoproteins with LH and CG. The LHCGR contains a large N-terminal extracellular domain with many leucine-rich repeats and sites for N-linked glycosylation involved in protein-protein interactions. The remainder of the receptor consists of seven-transmembrane domains and a C-terminal domain, which initiates signal transduction upon ligand binding to the extracellular domain. Interestingly, the LHCGR is encoded by 11 exons, of which the first 10 contribute to producing the large extracellular domain while the final exon generates the endodomain.

LHCGR expression has been studied in both gonadal and extra-gonadal (reproductive and non-reproductive) tissues. In the ovaries, LHCGR is expressed by multiple cell types including luteal, thecal, interstitial and granulosa cells. LHCGR is temporally expressed in the ovary during the ovarian cycle (Choi and Smitz, 2014). Following the LH surge, LHCGR levels decrease prior to ovulation and are subsequently induced during the mid-luteal phase. Finally, LHCGR levels decline along with CL regression. In the human endometrium, full length LHCGR is expressed during the proliferative and secretory phase, while a truncated form predominates in the decidua during early pregnancy (Banerjee and Fazleabas, 2010). Prior to pregnancy in the baboon, LHCGR expression is reduced in the proliferative phase but is induced in luminal and glandular epithelium during the secretory phase. During early pregnancy in the baboon, LHCGR localizes to the endometrial stromal cells surrounding the spiral arteries, associated with the onset of decidualization. Subsequently, LHCGR expression decreases as pregnancy progresses in the mature decidua, which parallels a decline in peripheral serum CG levels. Lastly, control of LHCGR signaling is mediated by both receptor desensitization due to conformational changes following continuous ligand binding and synthesis of an hCG/LH receptor binding protein with *endo*- and *exo*-nuclease activity leading to degradation of receptor mRNA (Cole, 2010).

Downstream LHCGR signaling is cell-type specific. In the ovary, ligand binding initiates a receptor conformational change resulting in activation of the classically-described stimulatory G-protein (G_s) (Cole, 2010). Subsequently, the G_s induces adenylate cyclase activity, yielding 3',5'-cyclic adenosine monophosphate (cAMP). Lastly, cAMP production initiates downstream signaling by protein phosphorylation and gene transcription, through activation of protein kinase A (PKA) and the cAMP responsive element, respectively. This signaling pathway is associated with classical effector pathways of CG, including transcription of cholesterol side-chain cleavage enzyme for progesterone secretion in luteal cells. Activation of alternate signaling pathways have also been described (Cole, 2010). For example, LHCGR signaling through phospholipase C (PLC) activation catalyzes phosphoinositide and production of secondary messengers inositol triphosphate and diacylglycerol. Significantly higher LH or CG levels, such as during the pre-ovulatory LH peak or in pregnancy respectively, favors the PLC pathway. Lastly, LHCGR activation mediates signaling through the extracellular signal-regulated protein kinases 1 and 2 (ERK1/2) and AKT pathways independent of PKA. This is particularly relevant in the setting of endometrial epithelial cells, which contain undetectable levels of cAMP following CG stimulation, and, rather, production of targets cyclooxygenase 2 (COX2) and prostaglandin E_2 (PGE₂) are mediated by ERK1/2 (Srisuparp et al., 2003).

While LH and CG both bind to the LHCGR, there are ligand-specific differences in receptor activation and downstream signaling (Choi and Smitz, 2014). CG acts as a super-agonist binding the LHCGR with greater affinity compared to LH. Downstream cAMP production is significantly greater in response to CG versus LH treatment. Alternatively, treatment of human granulosa cells with recombinant LH induces ERK1/2 and AKT signaling to a greater extent than CG. Additionally, the temporal stimulation of LHCGR by different ligand impacts cell response. For instance, chronic treatment with LH favors growth of granulosa cells in culture while chronic CG exposure impairs this process. Overall, the evolutionarily developed structural differences in LH versus CG, described in Section II, likely contribute to their distinct LHCGR binding capacity and downstream signaling.

Embryonic and Maternal Responses to Chorionic Gonadotropin

It is well established that CG functions to rescue the CL from regression during the establishment of pregnancy, which maintains progesterone production for embryo implantation. Spontaneous abortion, or pregnancy loss, will occur in the absence of this CL-derived progesterone. CG maintains the CL through a luteotropic role and as an inhibitor of luteolysis until the luteal-placental shift occurs (Srisuparp et al., 2001). Luteotropic mechanisms coordinated by CG include induction of genes responsible for steroidogenesis, such as steroidogenic acute regulatory protein, cytochrome P450 cholesterol side-chain cleavage, and 3 β -hydroxysteroid dehydrogenase. Anti-luteolytic properties of CG include maintenance of luteal blood flow, prevention of apoptosis, and regulation of tissue remodeling and macrophage recruitment.

While CG's role in maintaining CL progesterone production is well established, its secretion persists throughout pregnancy beyond the point where it is no longer required for progesterone secretion. Therefore, extra-gonadal functions for CG have been studied in depth (Fig. 1). Among these roles, CG coordinates the establishment of the maternal-fetal interface through directly regulating key events in both the uterus and the placenta (Cole, 2010; Srisuparp et al., 2001). Prior to embryo implantation, CG promotes endometrial receptivity, which was characterized using a baboon model of simulated pregnancy (Banerjee and Fazleabas, 2010; Fazleabas et al., 1999).

CG directly modulates endometrial compartment-specific functions before, during and after implantation (Banerjee and Fazleabas, 2010; Fazleabas et al., 1999). In the luminal epithelium, CG promotes the "epithelial plaque" reaction, characterized by hyperplasia and differentiation of epithelial cells at the implantation site. In the glandular epithelium, CG promotes the expression of factors that provide a favorable microenvironment for implantation. These factors include leukemia inhibitory factor (LIF), glycodelin and COX2. LIF regulates trophoblast cell adhesion and may be important for embryo invasion and placental development. Glycodelin, one of the most abundant glycoproteins present in the uterus during implantation, plays an important role in

Fig. 1 Gonadal and extra-gonadal roles of hCG.

immunosuppression and preventing fetal allograft rejection. COX2, an upstream regulator of prostaglandin synthesis, has been shown to produce PGE₂, which in part mediates vascular permeability for implantation.

In the endometrial stroma, CG induces α -smooth muscle actin (α -SMA) expression and delays stromal advancement, theoretically extending the window of implantation. α -SMA is initially expressed in endometrial stromal cells as part of the differentiation process from stromal fibroblasts towards their secretory phenotype. Upstream of α -SMA, NOTCH1 is induced by CG and coordinates pro-survival signaling in the endometrial stroma for decidualization (Afshar et al., 2012; Banerjee and Fazleabas, 2010; Strug et al., 2016). Interestingly, many of these described roles for CG throughout the endometrium requires synergism with progesterone receptor signaling (PGR) (Banaszak et al., 2000).

CG regulates mechanisms responsible for development of uterine vasculature and maintaining myometrial quiescence during pregnancy (Cole, 2010). LHCG is expressed on uterine spiral arteries to directly stimulate angiogenesis. Additionally, CG promotes recruitment of uterine natural killer (uNK) cells, responsible in part for remodeling the uterine vasculature. In the uterine myometrium, LHCG expression promotes growth to parallel that of the developing fetus. Also, CG signaling promotes myometrial relaxation through calcium channel modulation. Interestingly, the levels of hCG decline towards the end of pregnancy coinciding with increasing uterine contractions.

Lastly, CG exerts autocrine effects on the developing fetus and developing placenta (Cunningham et al., 2013). h-hCG, as mentioned previously, promotes cytotrophoblast invasion during implantation. CG directly acts to promote fusion of cytotrophoblast cells, which differentiate into syncytiotrophoblast cells during placentation. hCG plays a role in male sexual differentiation through stimulating fetal testicular development, by acting as a substitute for LH to promote leydig cell function and secretion of testosterone. While hCG levels are significantly lower in fetal circulation, there is a role for CG signaling in fetal growth. hCG coordinates umbilical cord growth, and LHCG is expressed in multiple fetal organs, such as the kidney and liver. Further, its expression is essentially absent in the mature, adult organs, suggesting a putative role for hCG in fetal growth.

Clinical Implications of CG and Future Perspectives

As described in "Introduction and Historical Perspectives" section, hCG has served as a clinical marker of pregnancy in women long before it was molecularly characterized. Today, hCG is an important marker for diagnosis of normal and pathologic pregnancy (Stenman et al., 2006). In many cases, patients identify pregnancy using reliable over the counter pregnancy tests. These tests use immunochromatography to provide semi-quantitative measurement of hCG metabolite hCG β core fragment from urine, detecting levels from 25 to 50 mIU/mL. However, the diagnosis of pregnancy is more accurately determined through quantitative

measurements using serum. These tests utilize the sandwich enzyme linked immunoassay (ELISA) method for direct measurement against pre-determined standards. hCG serum levels rise, doubling approximately every two days and peak by 10 weeks in pregnant women. After the hCG peak, serum levels slightly decline and plateau between 13 and 15 weeks gestation followed by a slight increase until 30–33 weeks (Stenman et al., 2006). Subsequently, hCG levels decrease until term, which may contribute to a reduction in myometrial relaxation and favor uterine contractions.

Clinically, doubling of hCG is predictive of successful embryo implantation, is particularly useful in the setting of patients undergoing treatment for infertility. Inappropriately rising levels of hCG or plateauing levels may indicate abnormal implantation, such as ectopic pregnancy or inevitable pregnancy loss. Typically, an intrauterine sac is visible on transvaginal ultrasound when serum hCG levels reach 1500–2000 mIU/mL, but failure to visualize a gestational sac at the “discriminatory zone” of 6000–7000 mIU/mL suggests an ectopic pregnancy. Following pregnancy loss, persistently elevated hCG levels may indicate multiple gestations or gestational trophoblastic disease (GTD). GTD refers to a wide range of pathologic pregnancies, ranging from molar pregnancy to choriocarcinoma. Serial measurement of hCG and hCG β fragment is performed for surveillance of GTD progression and for determining effectiveness of therapeutic management in affected patients. As mentioned earlier, measurement of hCG and its isoforms are clinically useful for detection of germ cell and non-trophoblastic malignancies.

During pregnancy, physicians may determine fetal aneuploidy risk through hCG measurement in combination with other markers (Stenman et al., 2006). Fetal aneuploidies include embryos with abnormal chromosome numbers, such as Down’s syndrome (Trisome 21). First trimester screening is performed between 11 and 13 weeks gestation and measures the levels of free β -hCG and pregnancy-associated plasma protein-A (PAPP-A) in combination with a specific ultrasonographic measurement, termed nuchal translucency. Second trimester screening, referred to as the “quad screen”, is performed between 15 and 18 weeks of pregnancy and measures four specific markers: free β -hCG, inhibin-A, estriol and α -fetoprotein. While these tests alone do not diagnose fetal aneuploidy, they provide a probability risk profile, which may prompt further diagnostic testing using cell-free DNA, chorionic villous sampling or amniocentesis.

Dysfunctional hCG signaling is associated with reproductive disorders affecting fertility (Choi and Smits, 2014). Although rare, polymorphisms in the hCG β -subunit gene are associated with recurrent miscarriage. Mutations in the LHCGR gene result in developmental defects with reproductive consequences, including pseudohermaphroditism and infertility. Additionally, increased risk for Polycystic Ovarian Syndrome (PCOS), associated with ovulatory defects and sub-fertility, has been associated with polymorphisms in the LHCGR gene. Endometriosis is a prevalent condition where endometrial tissue implants outside of the uterus and approximately half of women with this condition are infertile. In a well-established baboon model of endometriosis, treatment with hCG is associated with a blunted endometrial response (Sherwin et al., 2010). Specifically, endometriosis impaired the classical hCG-driven epithelial plaque formation and stromal α -SMA induction. These findings suggest an important mechanism for infertility in women with this debilitating disease.

Use of hCG in the management of infertile patients has been an important tool in assisted reproductive technologies (ART) and its expanded clinical use is currently being investigated for improving success rates. For many years, purified urinary hCG, and more recently recombinant hCG, has been used to induce the final stages of oocyte maturation and ovulation following ovarian stimulation as part of in vitro fertilization (IVF) protocols (Stenman et al., 2006). Additionally, systemic hCG may be administered following ovulation in IVF cycles for luteal support, with the intention of counteracting the negative impact of elevated estradiol levels from ovarian stimulation on endometrial function, which extends the implantation window. A role for hCG in priming the endometrium for embryo implantation and decidualization has been clearly presented (Afshar et al., 2012; Banerjee and Fazleabas, 2010; Fazleabas et al., 1999; Strug et al., 2016). More recently, it was shown that free β -hCG levels in embryo culture media positively correlate with implantation rates in women undergoing IVF treatment for infertility (Xiao-Yan et al., 2013).

Several studies have been performed to determine a therapeutic role for intrauterine hCG administration prior to embryo transfer in IVF cycles (Osman et al., 2016). While some studies have shown a positive effect on clinical pregnancy rates in infertile women, other studies have shown no impact on markers of IVF success. Clinical studies in women receiving intrauterine hCG following oocyte donation did show induction of classically-described endometrial hCG markers along with reduction in endometrial stromal advancement associated with controlled ovarian stimulation (Strug et al., 2016). Therefore, women undergoing ART may benefit from this therapy to counteract endometrial dyssynchrony from ovarian stimulation. Also, intrauterine administration of hCG may compensate for the lack of early hCG secretory functions with more blastocyst embryo transfers performed in IVF cycles. Altogether, hCG represents an evolutionarily developed messenger which establishes the initial stages of embryonic-maternal communication to support pregnancy. In addition to its important physiologic roles in pregnancy, hCG has served as a landmark tool for clinical diagnosis of normal and pathologic pregnancy. Lastly, its therapeutic potential in treatment of infertility remains an important topic of study to this date.

The Concept of Uterine Receptivity

In mammals, one of the most fascinating tissues is the uterus, whose major function is to accept implantation-competent blastocyst during a relatively short period defined as “the window of implantation.” Correspondingly, the window of uterine receptivity is defined as the limited time when the uterus is suitable for embryo implantation. This concept was first raised and established by the studies employing the embryo transfer technique in the 1960s (Dickmann and Noyes, 1961). In rats, while preimplantation embryos on day 4 of pregnancy (day 1 = vaginal plug) showed severe damage 9 h after transfer into a day 5 uterus, blastocysts obtained from pregnant mice at day 5 can implant normally after transfer to either day 4 or day 5 uteri, but not in the uteri beyond day 5 of pregnancy or pseudopregnancy. These findings suggest that the uterus is not constantly receptive to blastocysts and embryo implantation could occur only in a limited period. This notion was further confirmed by the experiments conducted in mouse (Paria et al., 1993). On the basis of these previous findings, the uterine sensitivity to implantation-competent blastocysts is classically divided into three stages: prereceptive, receptive, and refractory phase. During the prereceptive stage, the uterus is favorable for embryo development but not suitable for implantation, while the uterus can initiate implantation when there are competent blastocysts at the receptive stage. During the refractory stage, however, implantation-competent blastocysts could not implant in the uterus, and the uterus is adverse to the survival and development of blastocyst (Wang and Dey, 2006). In mice, the uterus on days 1–3 of pregnancy is conventionally considered to be in the prereceptive phase. On day 4 of pregnancy, the uterus becomes fully receptive following the priming actions of ovarian progesterone and preimplantation estrogen, whereas the uterus fails to initiate implantation by late day 5. Similarly, the first 7 days of the secretory stage in the menstrual cycle is considered as the prereceptive stage in humans, 7–10 days after ovulation, is considered as the receptive stage, and the rest of the secretory stage is defined as the nonreceptive stage (Wang and Dey, 2006). It has been generally accepted that uterine receptivity is one of the pivotal events that determine the success of pregnancy, since implantation-competent blastocyst only implants in the uterus at the receptive state and any disturbance to uterine receptivity would lead to compromised pregnancy outcomes, including retarded embryo development and pregnancy failure.

The Uterine Preparation for Receptivity

The uterine tissue is composed of three major layers: the outer muscle layer, the inner luminal epithelium, and the stromal bed in between. Actually, changes in the uterus during pregnancy are hormone-dominant events, controlled by the steroid hormones from the ovaries. In essence, synchronization of the two major ovarian steroid hormones, estrogen and progesterone, directs the uterus into the receptive state, which exhibits the morphological and functional changes in the uterine epithelial and stromal cells (Wang and Dey, 2006).

Morphological Changes for Uterine Receptivity

Microvilli and pinopodes

The uterine lumen is lined by a polarized epithelium overlying the underlying stroma and myometrium. One of the morphological changes of the luminal epithelium that marks the uterine transition from prereceptive state to receptive state is the retraction of apical microvilli on the apical side of the luminal epithelial cells. These microvilli were the focus of many early ultrastructural studies and underwent dynamic changes in appearance in response to ovarian hormones. With progesterone alone, short regular microvilli are characteristically present, whereas estrogen alone results in long thin regular microvilli. Under the influence of either hormone alone, changes in the apical plasma membrane are mostly limited to alterations in the height and frequency of microvilli. However, when progesterone and estrogen act together leading to uterine receptivity for embryo implantation during the periimplantation period, the apical plasma membrane of uterine epithelial cells undergoes a more marked structural change during the several days of early pregnancy. More specifically, it gradually loses regular microvilli and becomes very flat. The apical plasma membrane of uterine epithelial cells from a microvillus to the flattened profile is a morphological sign of uterine receptivity in many species, since the uterus that lacks the apical membrane flattening is unable to support embryo implantation. Moreover, it has been established that regular microvilli begin to return to the apical plasma membrane very soon after the period of uterine receptivity, further indicating the close association between the membrane changes and uterine receptivity (Murphy, 2004).

Another morphological change of the luminal epithelium is the presence of large apical protrusions, marking the uterine transition from prereceptive state to receptive state. This structure was first discovered in rats and mice by traditional electron microscopy and was named as a “pinopode” because of its pinocytotic function (Nilsson, 1958). In rats, it has been shown that the development of pinopodes synchronizes with the window of uterine receptivity, since the number of pinopode increases on day 4 of pregnancy and becomes more abundant on day 5 when the uterus enters the receptive phase and decreases rapidly during the

postimplantation period. Pinopodes, the bulbous cytoplasmic protrusion projections on the apical surface of the luminal epithelium, appear only during the receptive phase. Therefore, these pinopodes are the best-studied ultrastructural markers of uterine receptivity, which are believed to be helpful in the attachment of the blastocyst to the surface of luminal epithelium. Further studies revealed that the dynamics of pinopodes in the uterus are under the control of ovarian steroid hormones. Actually, the appearance of pinopodes was found to be strictly progesterone-dependent. As to the estrogen, it is dose-dependent. While treatment with high doses of estradiol together with progesterone before the development of pinopodes inhibited pinopode formation, low doses of estradiol did not interfere with the process until the fourth day of treatment. Moreover, when estradiol was given as a single injection after pinopode formation, both doses of estrogen were equivalent in inducing the regression of pinopodes 48–72 h later (Martel et al., 1991). These findings demonstrate the similar hormonal conditions for both pinopode formation and the attainment of uterine receptivity, further confirming that the appearance of pinopodes is a well-defined histological marker for uterine receptivity. However, it is still questionable about whether human pinopodes are clinically useful to delineate the period of endometrial receptivity, since pinopodes are present throughout the luteal phase of the menstrual cycle. However, there are evidences that pinopodes are most prominent during the putative implantation window, suggesting that the pinopodes in human endometrium are at least helpful to the determination of uterine receptivity.

Luminal closure

Luminal closure, defined as the closure of uterine lumen during embryo apposition prior to attachment, is another morphological landmark for uterine receptivity. This event supports a closer contact between the luminal epithelium and the blastocysts, which is essential for appropriate blastocyst apposition and subsequent attachment. In rodents, a generalized stromal edema under the influence of ovarian steroid hormones leads to the closure of uterine luminal epithelium (Wang and Dey, 2006). And progesterone has been demonstrated to be essential for the luminal closure, since uterine luminal closure failed to occur in mice missing FK506-binding protein 4 (FKBP52), a cochaperone for full functions of progesterone receptor (PR) in the uterus. However, the occurrence of luminal closure does not require the presence of blastocysts, since this phenomenon could also be observed in both the pregnant and pseudopregnant uteri (Wang and Dey, 2006). Moreover, it has been shown that the secretion and reabsorption of uterine fluid is important for the uterine luminal closure and these processes are at least under the control of two major gatekeepers: cystic fibrosis transmembrane conductance regulator and epithelial Na⁺ channel (Tu et al., 2014).

Functional Changes for Uterine Receptivity

During the establishment of uterine receptivity, functional changes are mediated by several factors such as adhesion molecules, cytokines, and homeotic proteins. Many of these molecules have been identified as potential markers of uterine receptivity. For example, the glycoproteins expressed in the luminal epithelium are thought to function as a uterine barrier that inhibits the interaction between the blastocyst and luminal epithelium at the time of attachment. Unmasking of these glycoproteins at the implantation site correlates with increased blastocyst adhesion to the uterus (Dey et al., 2004). MUC1, a mucin-type glycoprotein, is integrally located in the apical plasma membrane of the luminal epithelium before implantation, whereas its expression is timely downregulated during the receptive period, in agreement with the view that glycoproteins act as uterine barrier that inhibits implantation. In humans, on the other hand, the expression of MUC1 remains at high levels during the implantation window, which seems to be contradictory to the antiadhesion function of MUC1. One explanation is that the embryo utilizes MUC1-associated glycans, which has been demonstrated in rabbit implantation. Actually, in vitro experiment using human blastocyst and endometrial epithelial cells indicates that the embryo could induce paracrine degeneration of epithelial-expressed MUC1 at the implantation site. Thus, it appears that MUC1 must be locally removed at the implantation site prior to successful blastocyst attachment in both human and animal models.

The Embryonic Contribution to Uterine Receptivity

Embryo implantation involves the implantation-competent embryo and the uterus at the receptive state. In addition to uterus itself, the embryo also plays an important role in determining the implantation window. Although it is clear that the states of the blastocyst determined the implantation window (Paria et al., 1993), there is a long-standing quest for specific embryo-derived molecules and signaling pathways that can functionally influence the states of the uterus, especially the receptive state of the uterus. One such important molecule is heparin-binding EGF-like growth factor (HB-EGF), encoded by Hbegf gene. Global gene analysis of the blastocysts with differential competency for implantation revealed that HB-EGF is significantly upregulated during blastocyst activation (Hamatani et al., 2004), suggesting that this molecule might be important for embryo implantation. This was confirmed by the experiments employing the blastocyst-size Affi-gel beads presoaked with HB-EGF protein. When these beads were transferred intraluminally into a pseudopregnant uterus, they can induce the expression of HB-EGF in uterine cells surrounding the beads and increase vascular permeability, similar to the physiological changes induced by normal blastocysts (Hamatani et al., 2004). Interestingly, previous studies demonstrated that HB-EGF is also expressed in the luminal epithelium at the site of blastocyst apposition approximately 6 h prior to blastocyst implantation in mice, with increasing expression of its receptors ErbB1 and ErbB4 and ligand-receptor binding activities observed in the blastocysts that are competent for implantation. Signaling by HB-EGF back to the embryo, in turn, activates blastocyst differentiation required for embryo adhesion during subsequent attachment and invasion. These observations

Fig. 1 The autoinduction loop of HB-EGF/ErbB4 between the implantation-competent blastocyst and the receptive uterus.

also suggest that HB-EGF conducts an autoinduction loop between the implanting blastocyst and the uterus via paracrine and juxtacrine signaling (Fig. 1). In human, HB-EGF is highly expressed in the receptive endometrium, and its receptor ErbB4 is localized on the surface of the trophoblast in periimplantation blastocysts (Chobotova et al., 2002), indicating that HB-EGF/ErbB4 signaling also mediates the trophoblast–uterine epithelium interaction during implantation in humans.

The Hormonal Control of Uterine Receptivity

Pregnancy is a hormone-dominant process, including the establishment of uterine receptivity, a key event and stage during normal pregnancy. The hormones that direct the acquisition of uterine receptivity are mainly the ovarian steroids estrogen and progesterone, although the hormonal requirements for uterine receptivity are species-dependent. While Progesterone is essential for the establishment of uterine receptivity in nearly all the mammals studied so far, the requirements for ovarian estrogen are species-specific. For instance, estrogen is essential for the acquisition of uterine receptivity in the rat and mouse, while maternal estrogen is not required for implantation in some species such as rabbit, hamster, pig, and guinea pig, with the explanation that blastocysts in these species have the ability to synthesize estrogen, which may contribute to the activation of implantation process. In other species, such as nonhuman primates and the human, the functions of estrogen during implantation remain inconclusive (Wang and Dey, 2006).

Estrogen is essential for uterine receptivity in the progesterone-primed uterus in mice. On day 1 of pregnancy in mice, under the influence of preovulatory ovarian estrogen, the uterine epithelial cells undergo extensive proliferation that to some extent continue through day 2. Rising progesterone levels secreted from the newly formed corpora luteum initiate the proliferation of uterine stromal cells from day 3 onward. On the morning of day 4, when the uterus is at the prereceptive stage, the production of a small amount of estrogen is crucial for the uterus to attain receptivity. At this time, the uterine epithelial cells gradually lose their polarity, and the apical plasma membranes of the epithelial cells become smooth and flattened at the site of blastocyst apposition. Ovariectomy immediately before the preimplantation estrogen secretion on day 4 and daily supplementation of progesterone beginning on day 5 result in blastocyst dormancy and inhibition of implantation, whereas a single injection of physiological levels of 17 β -estradiol can induce the uteri from the neutral phase into the receptive state and renders the reactivation of blastocyst implantation (Zhang et al., 2013b). Based on these hormone profiles during the preimplantation period, exogenous estrogen and progesterone can also confer a receptive-stage uterus in ovariectomized mice.

In the uteri, estrogen and progesterone function mainly through nuclear estrogen receptors (ER) and PRs, respectively. Both the receptors have two main isoforms, known as ER α and ER β for estrogen and PRA and PRB for progesterone. Pharmacological and genetic evidences have revealed the requirements of ER and PR for the preparation of uterine receptivity. For example, administration of antagonists for either ER or PR before implantation efficiently abolished the establishment of uterine receptivity. Moreover, previous works using knockout mice for ER or PR have also demonstrated their differential functions during uterine physiology. The uterus with *Esr1* (gene encodes ER α) deletion is hypoplastic and unable to support implantation, whereas the uterus deficient for *Esr2* (gene encodes ER β) retains biological functions that allow for normal implantation, indicating the essential role of ER α during implantation. As to the PR, while mice with *Pgr* (gene encodes both the PRA and PRB with different promoters) deletion are infertile with defective ovarian and uterine functions, PRB-deficient females are fertile with normal ovarian and uterine responses, indicating that the functions of progesterone in uteri are primarily mediated by PRA (Zhang et al., 2013a).

The Establishment of Uterine Receptivity: Cell–Cell Interactions

Embryo implantation is a dynamic developmental event that involves a series of physical and physiological interactions among the blastocyst trophoblast and various endometrial cell types. Similarly, the establishment of uterine receptivity also involves

multiple cell–cell interactions between the luminal and glandular epithelium and the stromal cells, which are under the primary influence of ovarian steroids estrogen and progesterone (Zhang et al., 2013b).

The Uterine Epithelial–Stromal Interaction

As previously mentioned, synchronization of estrogen and progesterone directs the uterus into a receptive state that is accompanied by obvious morphological and functional changes in the epithelium (Zhang et al., 2013a). The interactions of ovarian progesterone and estrogen during uterine cell proliferation and differentiation are summarized in Fig. 2 and are discussed later.

Estrogen binds stromal ER α to stimulate the proliferation of uterine epithelium via paracrine factors

ER is expressed in both epithelial and stromal cells of the adult uteri. It was initially assumed that estrogen acts directly through the ER in the corresponding compartments. However, evidences from the experiments employing ESR1 knockout mouse models and stromal–epithelial separation/recombination systems (Cunha, 2008) demonstrated that estrogen could not stimulate epithelial proliferation in genetically recombined uterine tissue that lacks stromal ER α , even in the presence of epithelial ER α . The tissue-specific knockout techniques render the selective deletion of ESR1 in the uterine epithelium and further proved that stromal ER α is responsible for estrogen-induced epithelial proliferation. As to how the estrogen–ER α activity in the stroma induces the epithelial proliferation, paracrine actions of polypeptide growth factors are believed to be essential for the uterine response to estrogens, such as insulin-like growth factor 1 (IGF-1), epidermal growth factor (EGF), or transforming growth factor α . Specifically, IGF-1 is an important growth factor that could be induced and activated immediately in the uterine stroma upon treatment with estrogen. It is necessary for estrogen-induced uterine epithelial proliferation through IGF-1 receptor in the luminal epithelium. Moreover, stromal ER α is also sufficient for estrogen-induced downregulation of PR in the uterine epithelial cells.

Differentiation of uterine epithelial cells requires both epithelial and stromal ER α

Although it is the uterine stromal ER α not the epithelial ER α that is indispensable for estrogen-induced epithelial proliferation, the epithelial ER α is also essential for complete biological functions in the uteri, since selective deletion of uterine epithelial ESR1 resulted in compromised increase of uterine weight induced by estrogen and led to epithelial apoptosis after initial proliferation. Further evidence revealed that both the stromal and epithelial ER α are required for the functional differentiation of uterine epithelium, which could be indicated by such secretory proteins as lactoferrin, complement component C3, and MUC1 (Buchanan et al., 1999).

Progesterone functions through stromal PR to antagonize the epithelial proliferative response to estrogen and induce stromal proliferation

The phenotypes of uteri with Pgr-null mutation are similar to that of the uteri in the ovariectomized mice exposed to prolonged estrogen treatment. This finding revealed an essential role of PR in the uterus. Furthermore, recombination experiments using uterine tissue from Pgr-null mice demonstrated that stromal PR is required for progesterone to decrease the proliferation-promoting effect of estrogen on the uterine epithelial cells and promote the proliferation of stromal cells. And numerous molecules have been identified to mediate progesterone–PR signaling, such as immunophilin FK506-binding protein 4 (FKbp52), chicken ovalbumin upstream promoter-transcription factor II, the basic helix–loop–helix transcription factor, and heart and neural crest derivatives expressed transcript 2 (Hand2).

Fig. 2 The uterine epithelial–stromal interactions mediated by the ovarian progesterone and estrogen and their respective receptors.

Epithelial PR is also involved in stromal–epithelial cross talk

Despite the well-established concept that stromal PR mediates the antagonistic functions of progesterone on the epithelial proliferative response to estrogen, the important roles of epithelial PR in uterine biology were largely ignored. A recent study with Pgr deficiency in the uterine epithelial cells has demonstrated that epithelial PR is essential for epithelial expression of Indian hedgehog, which participates in the uterine stromal–epithelial cross talk. The absence of epithelial Pgr results in complete failure of pregnancy due to impaired uterine receptivity. This finding clearly demonstrated that epithelial PR is indispensable for the stromal–epithelial interactions during the establishment of normal uterine receptivity.

The Uterine Glandular–Epithelial Interaction

All mammalian uteri contain glands in the endometrium that synthesize and secrete substances essential for the survival and development of the conceptus. It has been shown that uterine glands and their paracrine-acting secretions have important biological roles in the establishment of uterine receptivity and blastocyst implantation (Kelleher et al., 2016). Of the substances secreted by uterine glands, LIF is one of the most important molecules, since LIF null mutation in mice led to infertility, defective uterine receptivity, and failed blastocyst implantation. The LIF is secreted into the uterine lumen where it binds the LIF-receptor complex composed of LIF receptor (LIFR) and gp130. The overlapping expression pattern of LIFR and gp130 in the luminal epithelium provides robust evidence for the paracrine nature of glandular LIF acting on uterine epithelial cells. Failure of gp130 activation in the luminal epithelium in LIF null mice reinforces the notion that LIF-driven glandular–luminal epithelial interaction is essential for normal uterine receptivity and blastocyst implantation. Although LIF has a well-recognized role to establish receptivity of the luminal epithelium for implantation, the role of many other genes expressed in the uterine glands has not been established. Moreover, future studies are needed to determine the role of the uterine glands and their secretions in paracrine interactions with the luminal epithelial cells.

The Flexibility of Uterine Receptivity

Since the uterine receptivity is determined by the ovarian steroid hormones estrogen and progesterone, the states of the uterine receptivity could be changed by the manipulation of the hormones estrogen and progesterone (Zhang et al., 2013a).

Estrogen Is Critical for Specifying the Duration of Uterine Receptivity

In rodents, estrogen is essential for the preparation of a progesterone-primed uterus to the receptive state. Ovariectomy conducted before preimplantation estrogen secretion on the morning of day 4 results in blastocyst dormancy and inhibition of implantation, also known as delayed implantation. This neutral uterine phase can be maintained by continued progesterone treatment but is terminated by estrogen injection. The impacts of different doses of estrogens on the length of implantation window have been explored using this delayed implantation model. For instance, estrogen at a low threshold level extends the window of uterine receptivity, whereas physiological higher levels of estrogen rapidly shut off the implantation window, transforming the uterus into a refractory state. The views that high levels of estrogen are detrimental to implantation are further supported by the findings that ovarian hyperstimulation leads to implantation failure and embryo resorption. In humans, the life span of fully developed pinopodes lasts maximally 48 h, suggesting a transient cell state in the receptive endometrium. Following ovarian stimulation with clomiphene citrate and human chorionic gonadotropin, pinopodes formed 1–2 days earlier than that in the natural cycles. Early pinopode formation caused by ovarian stimulation may suggest the shifting of the window for receptivity. Based on these findings, it is reasonable to speculate that reduced implantation in the cycles of in vitro fertilization could be due to asynchrony between the receptive endometrium and implantation-competent blastocyst that result from exposure to excessive estrogen.

Progesterone Supplementation Extends the Window of Uterine Receptivity

In mice, blastocysts can initiate implantation out of the normal “window” of uterine receptivity. For example, blastocysts can still initiate implantation when transferred on day 5 of pseudopregnancy, but implantation will not occur when normal blastocysts are transferred into day 6 pseudopregnant uteri. Exogenous progesterone supplementation can prolong the implantation window to day 6. However, deferred embryo implantation beyond the normal “window” of uterine receptivity leads to embryonic demise before birth in mice and is often associated with higher risk of early pregnancy losses in humans (Wang and Dey, 2006).

Introduction: A General Scheme of Growth Factor-Receptor Interaction

Growth factors are ligands that interact with cognate receptor(s) to activate intracellular signaling cascades. While most ligands utilize specifically fitted receptors for interactions, downstream conveyance of signals at the intracellular level often merge to regulate molecular events such as transcription and translation. Diverse changes subsequently occurring at subcellular levels are manifested as growth responses; thus, cells may proliferate, change shape, express specific genes to differentiate, or move. In a simplified version of a growth factor-receptor interaction, a factor, the ligand, approaches either in a secreted or in a juxtaposed form anchored in the membrane of another cell (Massagué and Pandiella, 1993). The target cell expresses the cognate receptor: secreted ligands can be reached via extracellular fluids but juxtaposed ligands require the presence of target cells within near reach. In many cases, receptors form multimers for the division of labor, i.e., one receptor directly interacts with a ligand, while the other receptor triggers an intracellular signaling cascade. For a specific family of growth factors, ligands often show promiscuity towards different receptors. Receptors generally undergo phosphorylation at certain residues on the cytoplasmic tail, triggering the recruitment of intracellular signaling mediators and leading to activation of intracellular signaling pathways (Citri and Yarden, 2006). Thus, the presence of specific ligands and cognate receptors at the same time within a reachable range, along with the right type of secondary signaling cascade, determines whether growth factor signals propagate or halt at a specific cellular context.

EGF: The First Evidence

Since the discovery of epidermal growth factor (EGF) in the submaxillary gland of mice in 1962 and the Nobel committee's recognition of the versatile actions of growth factors in 1986, the story behind the study of growth factors has been dramatic and expansive. As uterine preparation for implantation is accompanied by growth and differentiation of both embryonic and uterine cells, it was an expected course of investigation to look for expression and functions of newly discovered growth factors. EGF first entered the scene of scrutiny in the field of uterine biology because its function in the epithelial proliferation of other tissues was clearly pertinent to the implantation process involving close contact between a blastocyst and well-prepared uterine epithelium. Ovarian steroid hormones are seminal regulators of various aspects of uterine function (Huet-Hudson et al., 1989). Regulated expression of certain factors by ovarian steroid hormones therefore provides clues into understanding their roles. Early studies showed that isolated uterine epithelial cells proliferate in response to EGF (Tomooka et al., 1986) and that EGF expression is influenced by estrogen (Huet-Hudson et al., 1990). Thus, EGF became one of the first candidate mediators of estrogen activity in embryo implantation.

In initial investigations of EGF in uterine biology, several biochemical and molecular techniques were frequently used: expression of ligands and receptors at the mRNA and protein levels in vivo, receptor binding with radioactive isotope-labeled ligands using tissue extracts, and receptor phosphorylation (DiAugustine et al., 1988; Huet-Hudson et al., 1990; Lin et al., 1988). When gene-targeted mouse models became available in the 1990s, previous results demonstrating the involvement of growth factors in embryo-uterine interactions were confirmed (Lim and Dey, 2009).

Introducing the EGF Family

The family of EGF-like growth factors includes EGF, transformation growth factor alpha (TGF α), heparin-binding EGF-like growth factor (HB-EGF), amphiregulin, betacellulin, epiregulin, neuregulins, and epigen (Schneider and Yarden, 2014). These ligands were first produced in their membrane-anchored precursor forms and later proteolytically processed and secreted (Massagué and Pandiella, 1993). Both membrane-anchored and processed forms possess biological activities and functions. The EGF family of growth factors recognizes a set of receptor tyrosine kinases known as ErbBs. There are four ErbB receptors: ErbB1 (EGF receptor, EGFR), ErbB2, ErbB3, and ErbB4. They share a common structural feature bearing kinase activity which auto-phosphorylates their tyrosine residue, but differ in ligand specificity and kinase activity. Upon ligand binding, ErbB receptors form homo- or heterodimers and, similarly to other growth factor receptors, convey this signal to the intracellular compartment with kinase activity. Specific tyrosine residues on the cytoplasmic tails of each receptor are phosphorylated and intracellular signaling mediators are recruited (Citri and Yarden, 2006). There are exceptions to this standardized depiction: the ErbB2 receptor does not directly interact with a ligand and the ErbB3 receptor shows impaired kinase activity.

Multiple EGF-like ligands are expressed in uterine cells and blastocysts around the time of implantation. Table 1 summarizes the results from various investigators, focusing on uterine expression at the time of implantation in mice. Many EGF-like factors are expressed in similar spatial and temporal patterns. At the time of the blastocyst attachment reaction, HB-EGF, amphiregulin,

betacellulin, epiregulin, and neuregulin are expressed in the luminal epithelium and/or subepithelial stromal cells just surrounding the blastocyst. Information regarding the presence of ligands in secreted or membrane-anchored form, availability of the proper receptors, evidence of actual ligand-receptor interactions in the context of embryo implantation, and pregnancy-related phenotypes in knockout mouse models would provide clues for deciphering the roles for these factors in embryo implantation. While many of these ligands exhibit implantation-specific expression patterns and possess bioactivity for phosphorylating ErbB receptors (Lim et al., 1998; Lim et al., 1997), triple-compound knockout mice of EGF-TGF α -amphiregulin do not show implantation defects (Luetkeke et al., 1999). Overlapping expression thus suggests possible redundancy in functions. One EGF-like ligand, HB-EGF, satisfies all the above conditions. In this sense, HB-EGF deserves full attention among EGF-like ligands for its outstanding role in embryo implantation, and will be reviewed in the following section as a crucial mediator of implantation.

In contrast to the redundant roles of EGF-like ligands, gene deletion models of a single ErbB receptor leads to severe developmental defects, precluding the investigation of specific pregnancy phenotypes in adult female mice (Table 1). From an embryonic perspective of implantation, however, the absence of one ErbB gene in blastocysts does not hinder implantation of deficient embryos.

HB-EGF in Embryo Implantation

Near the time of embryo implantation, the uterus becomes edematous in the stroma, which contributes to closing of the uterine lumen. This closure is necessary for the close encounter of the blastocyst to the receptive uterine epithelium. When these components are close to each other, juxtacrine or paracrine ligand-receptor interactions become more effective. HB-EGF is unique in that its expression precedes the actual attachment reaction by several hours: its mRNA is first expressed at around 4 PM on day 4 of pregnancy just around blastocysts in the uterus (Das et al., 1994b). The presence of a blastocyst is required for this expression. Although the attachment reaction is many hours away, the luminal closure bringing the blastocyst near the luminal epithelium occurs at this point under hormonal influence. When blastocysts are brought closer, the membrane-anchored form of HB-EGF on the luminal epithelium can initiate juxtacrine interactions with ErbB receptors on blastocysts. Like other EGF-like factors, HB-EGF is initially produced in a membrane-anchored form, which can function in a juxtacrine manner with nearby ErbB receptors. When the transmembrane form (HB-EGFTM) is enzymatically processed for shedding into the extracellular space, it is now a mature form that functions in a paracrine manner. For implantation, both forms of HB-EGF appear to be important. The paracrine form of HB-EGF effectively increases embryonic growth and hatching in vitro when added to 8-cell stage embryos (Das et al., 1994a). In contrast, HB-EGFTM functions as an adhesion molecule, providing a tight connection between implantation-competent blastocyst and cells expressing cognate receptors. This was demonstrated by using 32D cells, a bone marrow-derived cell line, engineered to express HB-EGFTM on the surface. When HB-EGFTM-expressing cells were co-incubated with blastocysts, they adhered only to implantation-competent blastocysts.

HB-EGF exhibits dual specificity towards ErbB1 and ErbB4 and is capable of binding to heparan sulfate proteoglycans. All of these potential receptors are available for interaction during the early implantation phase (Lim and Dey, 2009). In the search to

identify the functional receptor for HB-EGF, the *Pseudomonas* exotoxin (PE)-conjugated system was devised (Paria et al., 1999). In this experiment, HB-EGF-PE or TGF α -PE was treated to day 4 normal or dormant blastocysts, and the cytotoxic effects were the greatest in HB-EGF-PE-treated day 4 blastocysts. In addition, HB-EGF-PE was toxic to most *Egfr*^{-/-} blastocysts. This observation also suggests that HB-EGF utilizes multiple receptors for its action on blastocysts. Although heparan sulfate proteoglycans can interact with HB-EGF, it is not considered the receptor for HB-EGF during implantation.

Functionally, HB-EGF is responsible not only for the attachment reaction, but also for the multiple uterine changes occurring during the early phase of implantation. Cellular and molecular changes provoked by a local factor can be examined in a simplified model of implantation using beads that are approximately the size of blastocysts. When HB-EGF-soaked beads were transferred to pseudopregnant uteri, they triggered a blue dye reaction, indicating increased vascular permeability occurring during the early implantation phase. This treatment also induced expression of HB-EGF itself in the luminal epithelium and differentiation of stromal cells into decidual cells (Paria et al., 2001). Consistent with these results, mice with uterine-specific deletion of the HB-EGF gene show compromised implantation (Xie et al., 2007). In summary, HB-EGFTM in the uterine luminal epithelium appears to interact with multiple receptors including EGFR and ErbB4 on implantation-competent blastocysts and contributes to the establishment of early implantation-related changes.

Other EGF-Like Ligands

Along with HB-EGF, amphiregulin, betacellulin, epiregulin, and neuregulins are other EGF-like ligands that are expressed near implanting blastocysts. Overlapping expression patterns of these ligands suggest that specific compensatory mechanisms may be operative (Das et al., 1997). As described above, amphiregulin deficiency does not cause any implantation-related defects, but amphiregulin is worth mentioning in the context of implantation biology because of two unique features. While most of these ligands are expressed at the time of the attachment reaction and persist as implantation proceeds, amphiregulin expression disappears immediately after the attachment reaction (Das et al., 1995). Additionally, amphiregulin is a rare example of progesterone-regulated gene expressed only in the uterine epithelium. Thus, amphiregulin expression is a widely used monitoring tool of progesterone responsiveness in the uterus of many gene-targeted mouse models with uterine defects.

Molecular Effects of HB-EGF-ErbB Signaling

We next describe the molecular events triggered by the HB-EGF-ErbB interaction during implantation. Both uterine epithelial and trophoblast cells near the time of implantation express HB-EGF and ErbB receptors. Thus, autocrine, paracrine, and juxtacrine interactions are all possible. Several studies have provided valuable clues to understanding the changes occurring when HB-EGF binds to its cognate receptors on target cells during implantation. HB-EGF binds to mouse blastocysts and opens specific Ca²⁺ channels, causing influx from the extracellular space. This effect is mediated by embryonic ErbB4, which is translocated to the apical surface of trophoblast cells at the relevant time. Intracellular Ca²⁺ accumulates in trophoblast cells by various means and then activates other intracellular signaling molecules, such as calmodulin and protein kinase C. The molecular and cellular changes mediated by HB-EGF-ErbB interactions promote trophoblast differentiation into an adhesion- and invasion-competent stage (Wang et al., 2000). When assessing trophoblast differentiation in vitro, one can use the outgrowth culture system for qualitative and quantitative evaluation. When a blastocyst is added to a culture well coated with an adhesion-promoting agent, trophoblastic cells attach and “outgrow” on the surface. The area occupied by growing trophoblast cells is measured to test the effectiveness of certain added agents as implantation-promoting factors. In this assay system, HB-EGF scores high. Thus, HB-EGF triggers molecular and cellular changes that closely resemble initial implantation in vivo. HB-EGF signaling also cross-talks with another signaling pathway in promoting blastocyst differentiation. Lysophosphatidic acid is a lipid signaling mediator with multiple functions in various physiological contexts, including embryo implantation (Ye and Chun, 2010). When added to blastocysts in vitro, lysophosphatidic acid induces accumulation of HB-EGF on the embryonic surface and promotes blastocyst outgrowth (Liu and Armant, 2004).

Now we will look into the second mechanism of HB-EGF action from the uterine perspective. One of the changes provoked by HB-EGF-soaked beads in the uterus is decidualization (Paria et al., 2001). The mechanism underlying this observation was examined in cultured uterine stromal cells. Here, HB-EGF treatment of cultured stromal cells causes characteristic changes in decidualization, i.e., proliferation, polyploidy, and binucleation. This effect was shown to be mediated by cyclin D3, a cell cycle molecule abundant in the uterine stroma (Tan et al., 2004).

Collectively, the above series of investigations verify the versatile involvement of this factor from the aspects of embryo-uterine interactions that further propagate into later stages of implantation (Fig. 1).

Conserved Roles for HB-EGF in Implantation: A Comparative Perspective

As presented above, extensive studies of mice have indicated that HB-EGF is a crucial mediator of embryo-uterine interactions during implantation. The mouse is often the most suitable system for functional validation of specific molecules because of the availability of various genetically modified model systems. Thus, initial findings from mice are tested further in different animal

Fig. 1 A schematic landscape of signaling by HB-EGFTM and mature HB-EGF. HB-EGF takes advantage of autocrine, paracrine, and juxtacrine modes of signaling to regulate both embryonic and uterine functions. Reproduced from Lim, H. and Dey, S. (2009). models, and these efforts help solidify the original idea and build a hypothesis of conserved functions across species. In this sense, expression of HB-EGF was examined in the endometrium of species such as rabbit, hamster, cow, baboon, and human.

Rabbit blastocysts initiate attachment on day 7 of pregnancy. At this time, HB-EGF is induced at the site where the blastocyst initially contacts the uterine epithelium. In pigs, multiple forms of HB-EGF are produced and secreted into the uterine lumen. In cows exhibiting blastocyst elongation, HB-EGF is also detected on day 13 of pregnancy. The baboon endometrium is another site of HB-EGF expression: herein, its expression is under the regulation of progesterone and chorionic gonadotropin. The implantation process in hamsters, unlike in mice, depends mainly on progesterone and does not appear to require ovarian estrogen. Although the hormonal requirement for implantation is distinct in mice and hamsters, the pattern of HB-EGF induction at their implantation sites are analogous; both species require the presence of a blastocyst. In both mouse and hamster uteri, however, estrogen is a strong inducer of HB-EGF expression in the luminal epithelium. Based on these observations, it appears that multiple factors are involved in HB-EGF expression, but the implantation-specific pattern of induction is under strict control of the blastocyst.

Relevant references regarding the potential roles of HB-EGF during implantation in other species are cited in a review article by Lim and Dey (2009). With respect to human studies, refer to the article written by Armant et al. (2015) and references therein.

Glossary

Blastocyst The stage at which the mammalian embryo will implant into the uterus. The *blastocyst* consists of the *inner cell mass*, a group of cells that will form the embryo proper and is enclosed by the hollow epithelial layer or sphere of cells, the *trophoblast*. The trophoblast initially mediates interactions between the developing embryo and the uterus. After implantation, the trophoblast, together with cells from the embryo, and uterus forms the placenta.

Decidua The cellular structure produced by extensive proliferation and differentiation of the uterine stroma (decidualization). It also contains many blood cells derived from the bone marrow. The decidua is formed after implantation and surrounds and supports the early growth and development of the implanting embryo. In mammals, where the trophoblast invades the uterus, such as in mice, the decidua restricts trophoblast growth and invasion.

Delayed implantation A physiological state that can be induced in about 40 mammalian species, such as mice, rats, and Roe deer. Blastocyst implantation is inhibited and embryo development arrested. By delaying implantation mammals regulate the duration of pregnancy, thus ensuring the young are born at the most optimal time and conditions for their survival.

Embryonic stem (ES) cells Developmentally totipotent cells derived from the mouse embryo's inner cell mass (ICM). These cells are cultured in vitro and can differentiate into many other cell types or produce entire mice when reintroduced into blastocysts, that are then transferred back into the uterus to develop to term. They have been primarily used to derive lines of mice ("knockout" mice) carrying mutations in any gene of interest.

Gene targeting A powerful technique used to introduce mutations into specific genes in ES cells grown in vitro. The ES cells are used to derive mice carrying the mutated gene so that its function can be studied in the whole animal.

Luminal epithelium The single layer of cells lining the cavity or lumen of the uterus. This tissue is central to regulating when blastocyst implantation occurs and in stimulating the underlying stromal cells to decidualize.

Introduction

In mammals, the attachment and then implantation of the developing embryo into the uterus is a unique, essential and a defining feature of their reproduction. Following fertilization, the zygote moves down the reproductive tract and undergoes a series of cleavage divisions that result in the formation of the multicellular blastocyst at the point the embryo moves from the fallopian tube into the uterus. As typified by the mouse and human, the blastocyst comprises some 60–100+ cells consisting of two types: the trophoblast, which will function as an early placenta, and the inner cell mass (ICM), which will form the embryo proper. For the blastocyst to survive, it must establish physical contact with the uterine tissues for it to receive nutrients to support its continued growth and development. In the uterus, the blastocysts attach to the luminal epithelium (LE), a single cell layered epithelium that lines the uterine lumen. Following attachment, the extent to which the embryonic trophoblast then invades the uterine tissues varies between species, with mouse and human embryos extensively invading the uterus, whereas in pigs and horses the embryo remains attached to the LE but does not invade.

An essential feature to successful implantation, is that the development of the pre-implantation embryo coordinates with the cellular and physiological changes occurring in the uterus in preparation for implantation during each reproductive cycle. Any asynchrony between the preparation of the uterus and embryonic development results in implantation failure and embryo loss.

The factors primarily driving the cellular changes in the uterus in its preparation to receive a blastocyst are the ovarian steroid hormones, estrogen (E2) and progesterone (P4). In mice, E2 release from the ovary stimulates extensive cell proliferation initially in the luminal (LE) and glandular epithelia (GE). Thereafter rising levels of P4 from the ovarian corpora lutea inhibit the E2 stimulated epithelial proliferation, and initiate a switch to stromal proliferation, together with the induction of cellular differentiation within the different uterine compartments. Most of these E2 and P4 mediated effects are now known to be due to the steroid hormones inducing the expression a variety of locally produced growth factors, including cytokines and their receptors that activate a variety of signaling pathways that then act on the different cell types in either a paracrine or autocrine manner (Finn and Martin, 1974). A key cytokine in the implantation process is Leukemia Inhibitory Factor (LIF) which is essential to regulating uterine receptivity and responsiveness to a potential implanting blastocyst (Stewart et al., 1992).

The Molecular Biology of LIF and Its Receptor

Leukemia inhibitory factor (LIF) is a secreted monomeric, glycosylated protein with a molecular weight (MW) of 32–62 kDa. It is initially synthesized as a 202 amino acid precursor that is then reduced to 180 amino acids by cleavage of a 22 amino acid peptide

from its N-terminus. The LIF protein is folded into a 4 α helix bundle with the molecular weight of the unglycosylated protein being 20 kDa. Though heavily glycosylated, glycosylation is apparently nonessential to LIF's biological activity. LIF is encoded by a single, 6 kb gene, consisting of three exons. The gene is transcribed as a 4.8-kb mRNA transcript, of which –3.2 kb at the 3' end is untranslated. In the human, the chromosomal locus of the LIF gene is 22q12.2 and in the mouse it maps to chromosome 11, band A1. LIF is a member of the interleukin-6 (IL-6) family of cytokines, that include IL-6 and 11, oncostatin M (OSM), cardiotrophin (CT), ciliary neurotrophic factor (CNTF) and cardiotrophin like cytokine (CLC). These factors share overlapping, as well as unique functions on many different tissues as they all utilize the transmembrane protein gp130 as a component of their specific receptors (Nicola and Babon, 2015).

LIF Receptor- β and gp130

LIF binds to the cell's surface via a heterodimeric high-affinity cytokine receptor consisting of two transmembrane proteins, the LIF receptor beta (LIFR β) and gp130. The human LIFR β precursor is a single pass transmembrane protein of 1097 amino acids, and maps to chromosome 5p13.1 and in the mouse to the proximal region of chromosome 15. At least three transcripts are transcribed from the gene in adult murine and human tissues. The largest transcript is 10–11 kb, and both it and the 5 kb transcript code for the full-length transmembrane protein. The other shorter form of 3 kb is generated by alternate splicing with the introduction of a novel stop codon truncating the mRNA, resulting in the synthesis of a soluble form of the receptor lacking both the transmembrane and intracellular domains. During pregnancy, synthesis of all three forms increases in the adult female liver resulting in elevated levels of the soluble form of the receptor appearing in the circulatory system which then peak at midgestation. The function of the soluble form is unclear, although it may act as an antagonist by binding to and sequestering LIF from the trans-membrane form of the receptor. Mutations in the LIFR β gene result the rare disease, Stuve-Wiedemann/Schwartz-Jampel syndrome that cause bone abnormalities and a dysfunctional autonomic nervous system that affects breathing and temperature regulation.

The other component of the high-affinity LIF receptor, gp130 (or IL6ST), is a 918-amino acid glycoprotein, with a 22-amino acid transmembrane domain and a 277-amino acid intracellular domain. This produces a protein with a predicted MW of 101 kDa, with glycosylation increasing the size to 130 kDa. The locus encoding gp130 maps to chromosome 5q11.2, which is homologous to the murine locus on Chr13. A pseudogene in humans is located on Chr17. In humans the gene is transcribed as a single 8.5 kb transcript, whereas in the mouse two transcripts of 7 and 10 kb are detected (Nicola and Babon, 2015).

LIF receptors are found in many different tissues including the liver, central nervous system, macrophages, bone, kidney, placenta, ICM of the blastocyst and the uterine epithelia. The binding of LIF to the LIFR β results in the non-covalent association of the complex with gp130 to create the high-affinity heterodimeric receptor complex (Fig. 1). In most cell types the formation of the high-affinity complex between LIF, LIFR β , and gp130 is required for signal transduction, although there is evidence that the LIFR β can function as a homodimer, without gp130, at inhibiting embryonic stem (ES) cell differentiation. The heterodimeric receptor complex itself has no intrinsic tyrosine kinase activity. However the cytoplasmic domains of LIFR β -gp130-LIF trimeric complex associate with at least three members of the Janus (JAK) kinase family, in particular, JAK1, JAK2, and TYK2. Activation of the JAKs, especially JAK1, is by transphosphorylation with one JAK1 member, that is attached to the cytoplasmic chain of LIFR β -gp130 dimer, phosphorylating another JAK1 bound to the other chain. The activated JAK kinases then stimulate, by phosphorylation, of at least three signaling pathways, the STAT pathway, p21ras/MAP kinase pathway, and PI-3 kinase pathway. Of these three pathways, it is the activation of the STAT pathway that is of most significance in the uterus (Fig. 1).

Phosphorylation of the bound JAKs recruits the STAT (signal transducer and activator of transcription) factors to the LIFR β -gp130-JAK1 complex. The STATs are a family of latent transcription factors present in the cytoplasm. Within the family, STATs 1, 3 and 5 are activated by gp130 cytokines, of which STAT3 is the predominant form with regard to LIF signaling in the uterus. The binding of STAT3 to the receptor complex results in its phosphorylation by JAK1. In turn the phosphorylated STAT3 forms a dimer which then translocates to the nucleus where it transcribes genes. Among the genes that STAT3 induces is SOCS3, which inhibits JAK/STAT signaling by binding to both gp130 and JAK1, and so acts in a negative feedback loop, shutting down the JAK/STAT3 and MAP kinase pathways (Fig. 1) (Nicola and Babon, 2015).

LIF and Female Reproduction

LIF was initially discovered as being a factor that simultaneously induced the differentiation and inhibited the proliferation of the myeloid leukemia cell line M1. Subsequently LIF was shown to be necessary to maintain cultured mouse embryonic stem cells (ES cells) in an undifferentiated state revealing a potential role in regulating mouse embryonic development (Williams et al., 1988). ES cells are the pluripotent stem cells established from the inner cell mass (ICM) of the mouse blastocyst and have been extensively used to both study mammalian development and as a vehicle for the modification of the mouse's genome. In mouse blastocysts, LIF transcripts are found in the trophoblast of the blastocyst, whereas the LIFR β and gp130 are detected in the ICM. In blastocysts, LIF expression in the trophoblast may act to maintain the cells of the ICM during implantational delay (embryonic diapause), a state in which, in some mammals, blastocyst growth is arrested, with cell proliferation and development ceasing in the embryo (Nichols et al., 2001). Such a strategy has evolved in some mammals to as to regulate the birth of the embryos to a time where food and resources are maximally available to the mother, so she can support the newborn's postnatal growth (Renfree and Shaw, 2000).

During post-implantation embryogenesis LIF is undetectable in the embryo proper, whereas the placenta and developing skeletal system both express the LIFR β , as does the developing central nervous system (CNS). Constitutive deletion of the LIFR β results

Fig. 1 Structure of the LIF receptor and activation of the JAK-STAT3 signaling pathway. The soluble cytokine LIF binds to the low affinity LIFRβ-gp130 (centre) making them dimerize to form the high affinity LIFRβ-gp130-LIF complex (left panel). This recruits the JAK kinases (Jak1) which autophosphorylate each other and in turn recruit the transcription factor STAT3. STAT3 is phosphorylated, dimerizes and enters the nucleus. The LIFRβ-gp130-LIF complex can also activate the ERK and PI3K pathways as well but these do not appear to be important in regulating LIF signaling during implantation. The STAT3 phosphorylated dimer binds to the promoters of various genes including SOCS3, initiating their transcription. SOCS3 protein can bind to the LIFRβ-gp130-LIF complex and block JAK kinase activity, so inhibiting the LIF mediated STAT3 signaling pathway (right panel).

in these tissues developing abnormalities that result in embryonic lethality either in utero, due to abnormal placental development or shortly after birth and correlates with defective development of the brain (Cheng et al., 2017; Ware et al., 1995). During postnatal development, LIF expression reappears in many tissues, as do the LIFRβ and gp130 receptors in many different adult tissues, such as the liver. Intriguingly, however LIF null embryos can develop into normal mice, suggesting that some other ligand, that utilizes the LIFRβ, is produced in the placenta and CNS during embryogenesis and is necessary for normal development of these tissues.

In adults, LIF is most highly expressed in the uterus, albeit transiently. In mice, uterine expression of LIF is biphasic, with the first peak occurring at ovulation (Day 0–1). Following mating, LIF expression declines but then rises again, starting on the morning of the fourth day of pregnancy (D4) that peaks around midday, before falling again to basal levels that persist throughout the rest of pregnancy (Bhatt et al., 1991). In the human uterus, LIF is first detected around Day 18 in the postovulatory phase of the menstrual cycle and persists until the end of the cycle. Unlike the mouse, there is no indication that LIF is expressed at the time of ovulation in women. In both the mouse and human uterus, LIF transcripts and protein are localized to the epithelium of the glandular endometrial glands (GE), and in the human LIF transcripts are also found in the LE (Cullinan et al., 1996). In women, LIF protein is detected in uterine washings, indicating that LIF is secreted into the uterine lumen. It is of significance that in both humans and rodents uterine levels of LIF peak at the exact time that the uterus becomes receptive to the embryo. Similar increases in LIF expression around the time of embryo implantation have been reported in many other species including the rabbit, hamster, rat, pig, cow, rhesus monkey, and western spotted skunk, indicating that this pattern of expression is a widespread among mammals (Cheng et al., 2002).

In mice the uterine expression of LIF is under maternal control and is not influenced by the presence or absence of embryos. Expression is detected on D4 in pseudopregnant mice that are physiologically primed for pregnancy, but have no embryos. LIF is not detected in mice during lactationally induced implantational delay, in which embryos are present in the uterus, but implantation is arrested, with the blastocysts entering a state of growth arrest and physiological dormancy. Once delay is broken, by weaning or removal of the suckling pups, LIF expression is induced and the dormant blastocysts are reactivated and implant (Chen et al., 2000).

In ovariectomized mice, where there is no production of endogenous E2 and P4 (due to the absence of the ovaries), uterine LIF expression can be induced by E2 injection, whereas injected P4 alone has no effect. In contrast, in rabbits, LIF expression is induced by P4 but not by E2. This reflects the differences in hormonal regulation in the rabbit, in which E2 is not required for the induction of implantation. LIF expression may be directly regulated by the action of the steroid hormone receptors because its promoter contains steroid response elements located upstream of the transcription start site. In transfection studies, the human LIF promoter

linked to a reporter gene is activated when cells are treated with P4. In both mice and humans, E2 stimulates the estrogen receptor alpha with transcription of the LIF gene being co-regulated with another transcription factor, the tumor suppressor factor p53 (Hu et al., 2007).

LIF Is Essential for Blastocyst Implantation

The coincidence between LIF expression in the uterus with the onset of embryo implantation, suggested that LIF might be an essential factor regulating this process. Direct evidence for this was established by the derivation of mice in which the LIF gene was mutated so that it was no longer functional.

Mice lacking a functional LIF gene develop to adulthood, although this can be influenced by strain background. Homozygous LIF-deficient males are fertile, however, homozygous females never produce any offspring despite repeated mating to males of proven fertility. In normal mice, by the fourth day of pregnancy, the blastocysts are distributed along the length of the uterine lumen. The mechanism by which this distribution and positioning is accomplished is not understood but may involve contractions of the uterine musculature, since there is no evidence for the existence of specific attachment sites in the uterus. During this time the cross-sectional shape of the lumen changes to a slit, with the top of the lumen orientated to the mesometrial side that is attached to connective tissue, fat, and the blood vessels supplying the uterus. The blastocysts are always located at the opposite (antimesometrial) side of the lumen and orientated such that the ICM faces the mesometrial side (Fig. 2A). The blastocysts are juxtaposed to the LE, with the LE almost entirely surrounding the blastocyst. However, at this stage, no firm attachment is established between the embryo and uterus as the blastocysts can be readily flushed from the uteri.

LIF deficient females ovulate eggs at normal numbers. Subsequently the eggs are fertilized, develop to the blastocyst stage and position themselves correctly along the length of the uterus in a manner that doesn't differ from normal LIF positive females. The phase at which the blastocysts are distributed along the uterus is referred to as the appositional stage. In normal mice, around the middle of the fourth day of pregnancy, full attachment or implantation commences with the luminal epithelium adjacent to the trophoblast being phagocytosed by the trophoblast resulting in the trophoblast coming into direct contact with the underlying stromal cells. By the fifth day the stromal cells, adjacent to the site of blastocyst attachment, have started to proliferate and initiate extensive morphological changes, that include an increase in size, and polyploidization, all of which leads to the formation of the primary deciduum. Decidua formation is accompanied by a localized increase in vascular capillary permeability and edema. Together, these changes produce a tissue that nourishes and supports the growth of the early post-implantation embryo, as well as restricting trophoblast invasion.

In LIF deficient females there is no evidence that the trophoblast invades the LE. Neither can any stage of decidua formation be induced, even after using different artificial procedures to induce decidualization. This revealed that LIF is not only required to initiate blastocyst implantation/invasion but is also required for the uterus to decidualize. This failure of the LIF deficient uteri to both allow blastocyst implantation and decidualization was not due to the uterus undergoing the appropriate patterns of cell proliferation and differentiation in preparation for implantation, since the LIF deficient uteri, when treated with E2 and P4, undergo normal patterns of cell proliferation and differentiation. Furthermore, post-ovulatory P4 levels increased at the same rate and to the same extent in the LIF-deficient mice as in normal females.

Fig. 2 Blastocysts in the murine uterus prior to implantation and within 24 h after the onset of implantation. (A) A blastocyst on D4 of gestation (arrow head) lies against the single cell layer of the luminal epithelium (L). Underneath the luminal epithelium is the stroma (S). The arrow head points to the inner cell mass (ICM) of the blastocyst that will form the embryo. The ICM is enclosed within the thin walled sphere of the trophoblast. (B) A blastocyst (arrow head) beginning to implant into the uterus. Note how the cellular density of the stroma (S) has increased as in forms the decidua. The luminal epithelium (L) is being phagocytosed by the trophoblast at the sides of the implanting blastocyst.

Conclusive evidence that the loss of LIF primarily affected the uterus was shown by the surgical transplantation of unimplanted LIF-deficient blastocysts (recovered from LIF deficient mothers mated to LIF deficient males) to the uteri of WT pseudopregnant recipients. In the pseudopregnant females the LIF deficient blastocysts implanted and developed normally to term. In the reciprocal procedure, transfer of WT blastocysts to pseudopregnant LIF-deficient females did not result in the implantation of the WT blastocysts in the LIF-deficient females. This revealed that the failure of implantation was due to a uterine defect rather than a defect in the blastocysts. This was further supported by the injection of recombinant LIF protein into pregnant LIF deficient females on the fourth day of pregnancy, which resulted in the blastocysts implanting and developing to term. Sterility in the LIF-deficient females is therefore due to an otherwise normal uterus not receiving the necessary signal (LIF) that both induces implantation and decidualization (Chen et al., 2000, Stewart et al., 1992).

The Uterine Luminal Epithelium Is the Target for LIF

The LIFR β and gp130 are expressed in both the GE and LE of human uteri. In the mouse, LIFR β levels in the LE progressively increase from the second day after mating and peak around D4 with the receptor being localized to the apical and basal sides of the LE. In contrast, gp130 is only transiently expressed in the LE around D4 and is not detected in the GE (Figs. 3A and B). In both mice and women there is no indication that LIFR β or gp130 are expressed at significant levels in the uterine stromal cells, with the possible exception of some hematopoietic cells such as macrophages or neutrophils. In the murine uterus, STAT3 is strongly expressed in the

Fig. 3 STAT3 signaling by the LIFR β -gp130-LIF complex in the Luminal epithelium of the mouse. (A) The LIFR β (green) is expressed in the luminal (LE) and glandular epithelia (GE) but not in the stroma (S). (B) Gp130 is only expressed at the apical surface of the LE. (C) Phosphorylated STAT3 (pSTAT3) translocates to the nuclei of the LE 1 h after LIF binding to the receptor complex. (D) However STAT3 though expressed in the GE does not translocate to the nuclei.

Fig. 4 A model depicting the progression of molecular changes in the murine uterus that lead to blastocyst implantation. On days 1–3 after mating the uterine epithelia and stroma undergo cell proliferation and differentiation that is driven by the ovarian steroid hormones estrogen (E2) and progesterone (P4). On Day 4 the blastocyst are in the uterus juxtaposed the epithelium (as shown in Fig. 3A). A transient increase in E2 (nidatory) that presumably activates the estrogen receptor and together with the p53 transcription factor induce LIF expression in the endometrial glands. LIF is secreted into the uterine lumen where it binds to the LIFR β -gp130 receptor complex on the surface of the LE (Fig. 2A and B). The binding of LIF to the LIFR β -gp130 complex activates STAT3 (Fig. 2C) that moves into the nuclei of the LE where it induces/represses the expression of some ~300 genes. By D5 the blastocyst has started to breakdown the LE and invade the stroma. The stroma undergoes decidualization that involves a range of cellular and molecular changes as seen in Fig. 3B and includes the expression of the LIF related cytokine IL-11 and the inflammation inducing factors such as prostaglandins (PGEs).

cytoplasm of the LE. Activation of the JAK-STAT pathway *in vivo* by LIF injection into mice, or when the LE was isolated as cell sheets from the uterus and then treated with LIF, revealed that STAT3 was phosphorylated and translocated to the nuclei of the LE (Fig. 3C and D). In addition, genetic ablation of either STAT3 or LIFR β specifically in the LE, as well as the mutation of the cytoplasmic domain of gp130, all result in an unresponsive uterus in which blastocysts could not implant.

LIF stimulation of the LIFR β /gp130 receptor, results in STAT3 activation and nuclear translocation within 15 min of LIF treatment. STAT3 translocation to the nucleus increases the levels in expression of some 250+ genes in addition to a further 50 genes whose expression decreases within 1 h after LIF treatment. This culminates in the activation or inhibition of numerous biological pathways in the uterus, involving signaling, the activation of 40+ transcription factors in the LE, changes in cell adhesion, cellular organization, immune status, metabolism, the secretion of other growth factors, cytokines and chemokines. The result of all these changes is that the blastocysts that are juxtaposed to the apical side of the LE start to implant (Rosario et al., 2014).

A summary for the action of LIF is proposed in Fig. 4, where LIF, secreted from the endometrial gland, binds to specific receptors on the LE. In turn this stimulates the epithelium to respond to the already closely apposed blastocyst by allowing trophoblast invasion of the uterus and for a second signal(s) to induce the underlying stromal cells to decidualize. However, given the extensive changes in gene expression that are induced in the LE by LIF, it is still necessary to identify the molecular factor(s) that directly initiate blastocyst activation/trophoblast invasion and which signaling pathway/factor(s), originating from the LIF stimulated LE initiate stromal decidualization.

Conclusions and Prospects

Cellular proliferation and differentiation in the uterus during the reproductive cycle, as well as embryo implantation, are primarily regulated by the steroid hormones E2 and P4, which in turn are regulated by the hormones of the hypothalamic–pituitary axis. However, it is now established that the complex cellular events at implantation are not only regulated by a few hormones secreted into the circulatory system but also by a cascade of locally produced peptide growth factors (cytokines, growth factors) and other small molecules, such as prostaglandins. This multitude of factors act to “amplify” the cellular and tissue responses to estrogen and progesterone by regulating the expression of a large number of genes through different signal transduction pathways and transcription factors. An increasing understanding of just which factors are crucial, such as LIF, how they interact with each other, and their control of gene expression in the uterus, are providing new opportunities to potentially regulate the fertility of many

mammals. In humans, a more pressing need is to gain a better understanding to some of the causes of “unexplained” infertility in women. There is now some evidence indicating that infertility in women due to defects at implantation is associated with disruption to the LIF regulated JAK-STAT pathway (Choi et al., 2016, Kang et al., 2009).

Interferons

Troy L Ott and Alan D Ealy, Pennsylvania State University, University Park, PA, United States; and Virginia Tech University, Blacksburg, VA, United States

Introduction

The term interferon (IFN) was first used by Isaacs and Lindenmann in 1957 to describe substances secreted by chicken chorioallantoic membranes exposed to influenza virus. The soluble interferon secreted into the culture medium rendered other membrane cultures resistant to virus challenge. This effect was termed virus “interference,” and served as the origin of the name interferon. More than 60 years later it is clear that interferons are members of the large cytokine family of evolutionarily conserved pleiotropic regulators of cellular function. Mammalian IFN are broadly classified into Type I, Type II, and Type III (Bayer et al., 2016). Type I IFN include alpha (IFNA), beta (IFNB), delta (IFND), epsilon (IFNE), tau (IFNT), and omega (IFNW). The Type II IFN class is represented by a single member, termed IFN gamma (IFNG), and the Type III IFN class contains at least three members that are known either as IFN lambda (IFNL) 1, 2, and 3 or as interleukin (IL) 29, 28A, and 28B. The roles of IFN are perhaps best described as components of the innate arm of the immune system and serve as early responders to invading pathogens. Interferons play a key role in reducing pathogen replication, and regulating immune responses to infection (Snell et al., 2017). However, a subclass of Type I IFN is now known to serve as vital controllers of early signaling between the developing embryo (conceptus) and the uterine endometrium in ruminant ungulates (Bazer and Thatcher, 2017). It is this role of interferons that will be reviewed here.

Evolution of Mammalian Interferons

The Type III IFNs are the most ancient class of IFN. They exist in birds, reptiles, and mammals. The Type I and II IFNs emerged after separation of mammals from other animals. The Type I IFN have fascinated scientists and clinicians for the past 60+ years and they were the first members of the family recognized to possess antiviral activity. Also, they have been long-recognized to contain different biological potencies against different pathogens. Some Type I IFN are general, broad spectrum immediate responders to pathogens while others contain more specialized functions, with some being expressed in specific cell types and reacting only with specific types of viruses (Ealy and Wooldridge, 2017). Multiple Type I IFN genes exist in mammals. For example, ruminant species (cattle, sheep, goats) that contain abundant and diverse rumen bacterial populations likely require a very robust immune system. Not surprisingly, cattle contain genes that encode 13 distinct IFNA, 6 IFNB, 24 IFNW, and between 3 and 6 IFNT (Walker and Roberts, 2009). Interferon gene duplication likely reflects the need for a variety of IFN to respond to a wide range of pathogens. The presumption is that as species emerged, they continued to duplicate and mutate IFN genes in their genomes in ways that improved their survivability. These mutations and duplications then provided genetic variation that likely facilitated the evolution of IFN signaling in the early communication between the conceptus and the uterine endometrium.

At least two Type I IFNs developed biological activities outside of the innate immune response. Both are produced exclusively by the developing placenta in a subset of even-toe hooved mammals (i.e., artiodactyla). In the pig, IFND has been studied as a potential facilitator of early pregnancy, although its specific function during pregnancy has not been elucidated in this species (Sang et al., 2014). Also, IFND is not found in all artiodactyla, which further complicates discovering its function. The second Type I IFN was identified in early placental cells of conceptuses from ruminant species (cattle, sheep, goats, bison, giraffe, yak, deer). The evolution of this IFN family is well-established (Ealy and Wooldridge, 2017). It emerged after ruminants diverged from other mammals approximately 36 million years ago. Since then, several duplication, rearrangement, and conversion events have produced multiple genes in each species. Cattle, for example, contain at least three and likely as many as six distinct IFNT genes. Several polymorphic forms of these genes are present in cattle, sheep, and goats. The reasons why multiple genes exist for IFNT in ruminants remains unclear. However, it is clear that the proteins expressed from these genes contain different biological activities, leading to speculation that multiple protein variants may be needed to fully activate the various physiological mechanisms needed for pregnancy to succeed.

The current theory for the origin of the IFNT gene is that it formed from an ancestral IFNW gene soon after ruminants diverged from other artiodactyla (Ealy and Wooldridge, 2017). Interferon tau and IFNW proteins have approximately 70% amino acid identity, establishing them as more closely related than the other Type I IFN. The evolutionary relatedness of IFNT to IFNA, IFNB and IFNW is shown in Fig. 1 (Ealy and Wooldridge, 2017). Clustering of each main IFN class is evident, and the IFNT cluster closer to the IFNW than the others. There also is a clear multiplication of IFNT genes after their divergence from other Type I IFN. Although IFNT contains a distinctive primary amino acid sequence, these differences in primary sequence do not prevent IFNT from sharing similar secondary and tertiary structure with other Type I IFNs. This enables IFNT to bind and activate the same receptors used by other Type I IFNs, but also likely accounts for differences in biological activity between Type I IFN. The emergence of IFNT likely occurred following at least one and potentially several mutation events. One noteworthy recombination event modified the 400-base sequence upstream of the translational start site so that the newly formed gene would be under the control of a trophectoderm-specifying promoter/enhancer. This permits IFNT genes to be expressed exclusively by the trophectoderm during

early pregnancy and renders them poorly inducible by virus (Ealy and Wooldridge, 2017). The IFNT also contains a unique 3' UTR region, but the functional significance of this region is not clear.

Discovery of Interferons' Role in Pregnancy

A role for interferons in pregnancy was established by several groups in the late 1960s and early 1970s. These groups were attempting to characterize signaling between the developing conceptus (embryo and associated membranes) and the uterine endometrium in ruminants (Bazer and Thatcher, 2017). Early work showed that a heat labile component of conceptus secretory proteins was able to extend corpus luteum (CL) function (inhibit luteolysis) when infused into the uterine lumen during a key stage of early pregnancy. Initially called Trophoblastin, Protein X and Trophoblast Protein-1, purified protein was prepared and sequenced leading to the identification of a unique, Type I, interferon designated interferon tau (IFNT; tau for trophoblast, its tissue of origin).

Interferon Signaling and Interferon Stimulated Genes

Type I IFN signal by binding the Type I IFN receptor, which consists of two subunits, IFNAR1 and IFNAR2. To date, there is no evidence for a distinct receptor mediating Type I IFN action in the uterus, nor is there evidence that response to IFN during early pregnancy is regulated by changes in receptor abundance on the endometrium (Hansen et al., 2017). Following binding to the Type I receptor, Janus kinase members JAK1 and TYK2 are reciprocally trans-phosphorylated to activate downstream signaling involving signal transducers and activators of transcription (STAT) proteins (Snell et al., 2017). Depending on the cell type and IFN bound, this can involve combinations of STAT1–6 that homo- or hetero-dimerize and act as transcription factors. The canonical Type I IFN STAT signaling pathway involves a heterodimer of STAT1 and STAT2 that translocates to the nucleus and binds interferon stimulated response elements (ISRE) on interferon stimulated genes to regulate transcription. Early transcribed genes include interferon regulatory factor 1 (IRF1) and IRF2. Interferon regulatory factor 1 induces transcription of other interferon stimulated genes (ISG), while IRF2 binds the ISRE and acts as a repressor of ISG thus serving as an “off” switch for IFN action. There are greater than 250 genes known to be activated by Type I IFN signaling. Among them are a large group of genes involved in the innate arm of the immune system, including myxovirus resistance 1 (MX1) and MX2, 2'5' oligoadenylate synthetase (OAS) and interferon stimulated gene 15 (ISG15). Following receptor binding, the combination of IRF2 action and internalization of the IFN receptor combine to limit Type I IFN action (Fig. 2).

Fig. 2 Schematic of IFNT signaling pathways. Reproduced from Demmers, K. J., Derecka, K. and Flint, A. (2001). Trophoblast interferons and pregnancy. *Reproduction* **121**, 141–149.

Similarly, IFNG, the lone Type II IFN signals via the JAK/STAT pathway. Receptor binding stimulates phosphorylation and activation of STAT1, which forms homodimers that bind gamma activated sequence (GAS) elements in promoters of IFNG-stimulated genes (Gough et al., 2008).

Interferon in Pregnancy

Interferon in ruminant pregnancy: Interferon tau is now well-accepted as the key signaling molecule initiating a cascade of biochemical events that culminate in rescue of the corpus luteum and maintenance of pregnancy (Bazer and Thatcher, 2017). Interferon tau is produced by the conceptus trophoderm during a defined period between 2 and 4 weeks of early pregnancy. Early studies showed that purified native or recombinant IFNT extend the function of the corpus luteum (CL) when infused into the uterine lumen. However, infusion of IFNT usually only extended CL function for several days or a few weeks, and never the entire length of a normal gestation. Therefore, additional conceptus signals are undoubtedly required to maintain the CL for the full length of gestation. The identity of these signals remains unknown, but is an area of active investigation. The proximal effect of IFNT is to alter the pattern of prostaglandin $F_{2\alpha}$ (PGF) production and/or release from the endometrium to block CL regression. This effect is mediated by IFNT suppression of endometrial expression of oxytocin receptors. Production of IFNT by the conceptus is transitory and must precede the onset of pulsatile secretion of PGF that is responsible for CL regression (referred to as an antiluteolytic mechanism). In domestic ruminants, conceptus production of IFNT continues for 1–2 weeks and then ceases (Bazer and Thatcher, 2017) (Fig. 3).

Interferon in porcine pregnancy: Interferon tau is not produced by the pig placenta. However, at least two other IFN are produced. These are IFND and the Type II IFN, IFNG. Neither IFN, alone or together, are considered to be an antiluteolytic signal in pigs (Mathew et al., 2016). However, these two IFN, along with conceptus estrogen and other cytokines are thought to promote uterine receptivity, uterine secretion and to modulate immune cells in the endometrium during early pregnancy.

Interferon in rodent pregnancy: There is no evidence that an IFNT gene exists in rodents or any species outside of the ruminants. Rodent conceptuses produce antiviral agents, but immunoneutralization studies indicate that this activity is not caused by IFNA or IFNB (Cross et al., 1990). IFNG may be responsible for this activity. It is produced by post-implantation mouse placentae (Chen et al., 1994). Also, the IFN-responsive protein, ISG15, is highly expressed during early pregnancy in the mouse uterus and is covalently linked to other proteins in a process referred to as ISGylation. This reaction is thought to alter protein half-life or function in ways that facilitate implantation and/or serve as a defense to infection during pregnancy (Hansen et al., 2017).

Interferon in human pregnancy: Human placental tissue has the capacity to produce IFNA, IFNB, IFNW, and IFNL as early as the first trimester (Bayer et al., 2016). In contrast to ruminants, however, there is no evidence that IFN play a role in rescuing CL function. The human conceptus produces a placental gonadotropin, chorionic gonadotropin, that acts directly on the CL via the circulation to support progesterone production. IFN production by the human placenta is thought to largely play a role in inhibiting maternal to fetal viral infection and to enhance adaptive immunity (Racicot and Mor, 2017).

Summary

Interferons are a large family of related cytokines first identified by their ability to confer resistance to viral infections. They are firmly established as components of the innate arm of the immune system providing rapid and broad protection against a wide variety of invading pathogens. Of the three subfamilies, Type I IFN show the greatest diversity with over 20 family members. Interestingly, one member of this class, interferon tau, evolved to function as a signaling molecule between the early conceptus and the maternal uterus in ruminant ungulates. This interferon, IFNT, is necessary and sufficient to rescue the function of the corpus luteum during early pregnancies in these species. In addition, it is clear that other IFN family members, including IFNA, IFNB, IFNG, and IFND, are produced by placentae of rodents, humans, and swine. Their functions are less well-understood, but they likely play roles in modulating the immune function at the fetal–maternal interface and protecting the fetus against infection by maternal pathogens.

Introduction

Trophoblast cells are epithelial cells that contribute to the specialized functions of the placenta. They are essential for viviparity, allowing for growth and development of the fetus within the confines of the uterus. The term trophoblast originated with the noted Dutch embryologist, Ambrosius A.W. Hubrecht, during his efforts to describe placental development in the hedgehog, *Erinaceus europaeus* (Hubrecht, 1889; Pijnenborg and Vercruysse, 2013). Selection of the name was based on the perceived nutritive role of the cell population supporting embryonic development within the female reproductive tract. Unlike most organ systems the placenta exhibits greater anatomical diversity among species and thus comparative placentation is plagued with species-specific nomenclature. Nonetheless, trophoblast is a term that has endured and in its many formulations has been used to describe cellular constituents of the placenta. In this article, we discuss this vital cell lineage, addressing its developmental origin, specializations, and critical roles in placenta function. Our focus is on trophoblast cells that contribute to hemochorial placentation, a process observed in several species including human, mouse, and rat, with some limited information regarding ruminant trophoblast cells.

Developmental Origin of Trophoblast Cells

Trophoblast cells arise as the first landmark differentiation event during embryonic development. Fertilization reconstitutes a diploid chromosomal composition through fusion of a haploid sperm with a haploid egg, forming a one-cell embryo and activating cell division. As the embryo expands in size and cell number, niches change, and cells on the outer surface of the embryo are directed to a trophoblast cell fate, which fundamentally redirects their functional properties and developmental potential. At the blastocyst stage, embryonic cells are partitioned into two compartments: the outer trophoblast (early trophoblast cells) and a cluster of cells it surrounds referred to as the inner cell mass (Fig. 1). Further trophoblast cell lineage development is stimulated through interactions with the inner cell mass and its derivatives as well as the maternal uterine environment.

Molecular Regulation of Trophoblast Cell Lineage Development

Considerable mechanistic insights underlying trophoblast cell development have been derived from experimentation with rodent models. Such efforts have been spurred by the capacity for in vivo experimental mutagenesis, especially in the mouse, and the investigation of in vitro trophoblast cell culture models with stem cell properties (Faria and Soares, 1991; Tanaka et al., 1998; Asanoma et al., 2011). Key components of signaling pathways have been defined and include transcriptional regulators required for development of the trophoblast cell lineage (Pfeffer and Pearton, 2012; Latos and Hemberger, 2016). TEAD4, CDX2, EOMES, GATA3, TFAP2C, and several more transcription factors have been shown to be vital to the establishment of the trophoblast lineage. Expansion of the trophoblast lineage is driven by fibroblast growth factor and transforming growth factor beta (Activin/Nodal) signals secreted from the inner cell mass and its derivatives, which act on neighboring trophoblast stem and progenitor cell populations. These efforts provided the basis for developing conditions for inducing trophoblast stem cell development from mouse embryonic fibroblasts (Benchetrit et al., 2015; Kubaczka et al., 2015). Introduction of a core group of three transcription factors (EOMES, GATA3, and TFAP2C) into fibroblasts activated the trophoblast stem cell program. The resulting induced-trophoblast stem cells behave like trophoblast stem cells isolated from mouse embryos, including: (i) transcriptomic and epigenomic profiles, (ii) in vitro differentiation into specialized trophoblast lineages, and (iii) chimeric contributions to the developing placenta when re-introduced into early embryos. Although, this collective mechanistic information has illuminated our understanding of the derivation of the mouse trophoblast lineage, it is evident that this process lacks complete conservation across mammals (Berg et al., 2011; Niakan and Eggan, 2013; Blakely et al., 2015).

Insights into the regulation of human trophoblast cell lineage development have lagged. Human trophoblast stem cell cultures comparable to rodent in vitro models have not been established and ethical constraints prevent in vivo genetic manipulation strategies. An assortment of different in vitro human trophoblast cell culture systems has expanded our understanding of trophoblast cell development but each has limitations (Lee et al., 2016). A serendipitous finding by Thomson and colleagues working with human embryonic stem cells provided a potential in vitro model system for trophoblast cell lineage investigation (Xu et al., 2002). Human embryonic stem cells exposed to bone morphogenetic protein 4 differentiate into cells with a trophoblast cell phenotype, representing an in vitro model system suitable for dissecting potential molecular mechanisms controlling human trophoblast cell lineage development (Xu et al., 2002; Ezashi et al., 2012; Li and Parast, 2014). It has been proposed, that the resulting differentiated cell population reflects an early stage of trophoblast development. However, validation of such a hypothesis has been problematic due to the limited availability of adequate in vivo reference material.

Fig. 1 Schematic presentation of modes of trophoblast cell differentiation. Trophoblast stem and progenitor cells arise from trophectoderm of the blastocyst and give rise to differentiated cell lineages. Differentiated cell types include: invasive trophoblast (endovascular and interstitial), spongiotrophoblast, glycogen trophoblast cells, trophoblast giant cells, syncytiotrophoblast, and binucleate cells. Trophoblast giant cells, syncytiotrophoblast, and binucleate cells are formed through specific modes of differentiation (endoreduplication, fusion, and acytokinetic mitosis respectively) as indicated by the labeled arrows. Binucleate cells fuse with uterine epithelial cells to form trinucleate heterokaryons. The species in which the differentiated cell types exist are indicated to the right of each cell type.

Trophoblast Cell Specialized Functions

Viviparity is a successful reproductive strategy; however, it poses significant challenges. The developing embryo/fetus needs access to nutrients and protection from the adversities of the maternal environment. Trophoblast cells engineer essential solutions to meet these needs and facilitate adaptation of the embryo/fetus to intrauterine life. Acquisition of specialized trophoblast cell functions are accomplished through multilineage cell differentiation, which is to say that not all trophoblast cells are alike in form or function. Trophoblast cells differentiate from trophoblast stem cell populations and become specialized to address the critical functions of the placenta which include: (i) acquisition of nutrients from the mother and delivery to the fetus; (ii) protection from adversity associated with exposure to the maternal environment.

Trophoblast cells acquire several specializations to precondition the uterus in support of embryonic/fetal development. They target the uterine parenchyma and especially the uterine vasculature where they transform uterine arteries through disorganization of associated smooth muscle and replacement of arterial endothelium (Kaufmann et al., 2003; Pijnenborg et al., 2006). These efforts are carefully orchestrated through acquisition of properties facilitating trophoblast cell movement, dissolution of extracellular matrices, invasion into the uterine parenchyma and vasculature, and endothelial cell mimicry (Harris, 2010). In doing so, subpopulations of trophoblast cells transform uterine vascular conduits from high resistance and low capacity vessels to low resistance and high capacity vessels (Harris, 2010). Thus, attenuating flow rates and the subsequent damaging effects of shear stress on the uterine endothelium and placenta. Trophoblast cells are also capable of facilitating fetal nutrient delivery through two mechanisms: (i) production of hormones that sustain the gestational state and redirect maternal metabolism (Porter et al., 1982; Newbern and Freemark, 2011; Carter, 2012); (ii) expression and activities of nutrient transporters (Carter, 2012; Dilworth and Sibley, 2013; Diaz et al., 2014).

Cellular mechanisms underlying fetal protection are fundamental properties of trophoblast cells. Importantly, trophoblast cells help modulate the maternal immune system by evading and abating the triggers of immune rejection (Erlebacher, 2013) and providing an essential barrier function (Burton et al., 2016). Specialized trophoblast cells prevent adverse exposures through the

biotransformation of potentially harmful agents and facilitate their exodus via efflux transporters (Hakkola et al., 1998; Joshi et al., 2016).

One of the most important properties of the placenta is its plasticity. Plasticity is achieved through marshaling trophoblast stem and progenitor cell populations to expand and/or differentiate along pathways conducive to maximize adaptive abilities (Soares et al., 2014).

Collectively, trophoblast cell specializations provide the placenta with functionality ensuring successful in utero survival and growth of the embryo and fetus.

Trophoblast Cell Differentiation

There is an assortment of differentiated trophoblast cell types (Table 1 and Fig. 1). Trophoblast cells are specialized to control early stages of embryonic development by interacting with maternal uterine structures to establish the interface with the fetal vascular conduit. Some differentiated cell types define specific features of placentation and are characteristic of a species.

Trophectoderm

Trophectoderm corresponds to the outer cell layer of the mammalian blastocyst-stage embryo and represents the source of stem and progenitor cells for further trophoblast development. Two additional key functions are ascribed to trophoctoderm: (i) facilitating interactions with uterine epithelium at embryo implantation; (ii) creating a protective environment for inner cell mass/epiblast development (Biggers et al., 1988; Aplin and Ruane, 2017).

Differentiated Trophoblast Lineages: Mouse and Rat

The placenta of the mouse and rat are organized into two compartments: (i) junctional zone; (ii) labyrinth zone (Soares et al., 2012).

The junctional zone represents the interface with the maternal environment and is composed of several differentiated trophoblast cell types, including: trophoblast giant cells, glycogen trophoblast cells, spongiotrophoblast cells, and invasive trophoblast cells. Trophoblast giant cell development is dependent upon the transcription factor HAND1 (Riley et al., 1998) and arises through endoreduplication, a process where DNA synthesis continues while mitosis is interrupted, resulting in the formation of large polyploid/polytene cells. CDKN1C (p57kip2), a cyclin-dependent kinase inhibitor, has been implicated in the process of endoreduplication (Ullah et al., 2008). The trophoblast giant cell is prominently situated at the uterine-placental boundary and is the major endocrine cell of the placenta, possessing the capacity to produce both steroid and peptide hormones (Soares et al., 1996). Trophoblast giant cells are also located elsewhere in the placenta. Their positioning within the placentation site

Table 1 Differentiated trophoblast cell types

Cell type	Species ^a	Placentation site location	Principal function(s)
Trophectoderm	Mouse, rat, human, sheep, and cattle	Outer cellular layer of blastocyst	Embryo implantation; inner cell mass/epiblast protection; source of trophoblast stem and progenitor cells
Trophoblast giant cell	Mouse, rat	Junctional zone: uterine-placental interface (primary), labyrinth zone (secondary)	Endocrine activity: steroid and peptide hormonogenesis
Glycogen trophoblast cell	Mouse, rat	Junctional zone (transient)	Energy reserve
Spongiotrophoblast cell	Mouse, rat	Junctional zone	Endocrine activity: peptide hormonogenesis
Endovascular invasive trophoblast cell	Mouse, rat, and human	Intrauterine: intravascular; extravillous compartment (human)	Uterine spiral artery restructuring
Interstitial invasive trophoblast cell	Mouse, rat, and human	Intrauterine: extravascular; extravillous compartment (human)	Placental anchor; uterine stroma remodeling
Syncytiotrophoblast	Mouse, rat, and human	Labyrinth zone (mouse, rat); villous compartment (human)	Barrier/transport (mouse, rat, human); endocrine activity: steroid and peptide hormonogenesis (human)
Uninucleate trophoblast cell	Sheep, cattle	Cotyledon	Endocrine activity: interferon tau; source of trophoblast stem and progenitor cells
Binucleate trophoblast cell	Sheep, cattle	Cotyledon	Endocrine activity: steroid and peptide hormonogenesis
Trinucleate cell	Sheep, cattle	Uteroplacental interface; uterine epithelial cell-binucleate cell heterokaryon	Endocrine activity: steroid and peptide hormonogenesis

^aDifferentiated trophoblast cell types found in mouse, rat, human, sheep, and cattle.

influences their behavior (Soares et al., 1996; Simmons et al., 2007). Glycogen trophoblast cells appear transiently during the last week of gestation and are conspicuous in their accumulation of glycogen and thus, at least in part, serve as a placental energy reserve (Coan et al., 2006). There is some thought that glycogen trophoblast cells migrate out of the junctional zone and infiltrate the uterine decidua; however, precise lineage tracing data is lacking. Spongiotrophoblast cells contribute to the endocrine functions of the placenta. They actively secrete a range of peptide hormones, including members of the expanded prolactin family (Soares, 2004). Finally, the junctional zone serves as a reservoir for invasive trophoblast cells that infiltrate the uterine parenchyma and coordinate remodeling of the uterine arterial vasculature (Ain et al., 2003). Until midgestation, the movement of trophoblast cells is similar in the mouse and rat. Endovascular invasive trophoblast cells enter the vasculature and are confined to the decidua. After midgestation, interstitial invasive trophoblast cells move into the uterus. In the mouse, interstitial invasive trophoblast cells are restricted in the depth of their invasion to the decidua, whereas in the rat both endovascular and interstitial invasive trophoblast cells extend beyond the decidua and deep into the uterine mesometrial compartment (Ain et al., 2003; Soares et al., 2012). Hypoxia/hypoxia inducible factor signaling is an effective activator of the invasive trophoblast cell lineage (Chakraborty et al., 2011, 2016). Furthermore, the junctional zone and its cellular constituents exhibit robust responses to genetic and environmental manipulations (Konno et al., 2007; Rosario et al., 2008; Soares et al., 2012).

The labyrinth zone is positioned at the fetal interface and consists of trophoblast progenitor cells that fuse to form multinucleated syncytiotrophoblast or as gestation progresses differentiate into trophoblast giant cells via endoreduplication (Walentin et al., 2016). Labyrinthine syncytiotrophoblast comprise two layers (syncytiotrophoblast layers I and II; Walentin et al., 2016), which form the barrier that regulates the entry of solutes into the fetal vasculature and possesses a robust complement of transporters (Georgiades et al., 2002; Dilworth and Sibley, 2013). The syncytiotrophoblast layers are contiguous, with syncytiotrophoblast layer I located proximal to trophoblast cells lining the maternal blood space and syncytiotrophoblast layer II situated next to the fetal vasculature. Syncytiotrophoblast arise through a process of cell fusion orchestrated by endogenous retroviral envelope genes referred to as syncytin-A (SYNA) and syncytin-B (SYNB; Dupressoir et al., 2012). SYNA drives the fusion of syncytiotrophoblast layer I, while SYNB promotes the fusion of syncytiotrophoblast layer II (Dupressoir et al., 2011). The glycosylphosphatidylinositol-anchored cell surface protein LY6E is a candidate receptor for the fusogenic properties of SYNA (Bacquin et al., 2017). Trophoblast giant cells appear in the labyrinth zone during the last week of gestation where they line maternal blood spaces adjacent to syncytiotrophoblast layer I and exhibit distinctive endocrine properties (Soares et al., 1996; Simmons et al., 2007).

Differentiated Trophoblast Lineages: Sheep and Cattle

Placentation in sheep and cattle is classified as synepitheliochorial, which differs from hemochorial placentation found in the mouse, rat, and human (Wooding and Burton, 2008; Roberts et al., 2016). The synepitheliochorial placenta consists of multiple placentation sites (placentomes) dispersed throughout the uterus. Each placentome is subdivided into trophoblast-rich cotyledon tissue and an adjacent caruncle composed of uterine tissue. This type of placentation exhibits a maximal number of maternal and extraembryonic cell layers constituting the placental barrier and an unusual differentiated cell type, the binucleate cell (Wooding, 1992). Binucleate cells arise from uninucleate (also called mononucleate) trophoblast cell progenitors through a process referred to as acytokinetic mitosis. During acytokinetic mitosis, uninucleate trophoblast cells undergo DNA synthesis and karyokinesis, without proceeding to cytokinesis (Klisch et al., 1999). Binucleate cells are migratory, secrete both steroid and peptide hormones, and are capable of fusing with uterine epithelial cells to form trinucleate cells consisting of binucleate trophoblast cell-uterine epithelial cell heterokaryons (Wooding, 1992).

Differentiated Trophoblast Lineages: Human

The early human implantation site is characterized by the formation of a trophoblast syncytium (Huppertz, 2008). This structure, which presumably arises through cell fusion of trophoblast cells, envelopes the developing embryo and is embedded within the uterine parenchyma. The early trophoblast syncytium provides a potentially vital role in the establishment of pregnancy. Syncytiotrophoblast of early placentation has been an ethical challenge to investigate in the human. Alternatively, the guinea pig exhibits parallels in early trophoblast development (Enders and Schlafke, 1969) and may represent a useful model for examining the biology of this early stage of hemochorial placental development.

Trophoblast cells of the mature human placenta can be partitioned into two major compartments: (i) extravillous; (ii) villous (Maltepe and Fisher, 2015).

Extravillous trophoblast cells consist of invasive trophoblast cells and their progenitors, which are situated within extravillous trophoblast cell columns (Velicky et al., 2016); structures analogous to the junctional zone of the rodent placenta. Invasive trophoblast cells are further classified based on their entry route into the uterine parenchyma. As described above, interstitial invasive trophoblast cells infiltrate between uterine vasculature, whereas endovascular invasive trophoblast cells migrate into and replace the endothelium of uterine spiral arteries. Human invasive trophoblast cells exhibit functionality analogous to invasive trophoblast cells of the mouse and rat (Pijnenborg et al., 1981, 2006; Soares et al., 2014). Several signaling pathways have been implicated in the regulation of extravillous trophoblast cell development and function (Knöfler, 2010).

Villous trophoblast cells consist of progenitors referred to as cytotrophoblast, which fuse to form syncytiotrophoblast (Aplin, 2010). Cytotrophoblast are most abundant during early phases of gestation and decline in number as gestation advances. They

are located beneath the syncytiotrophoblast layer, which borders maternal blood spaces. Syncytiotrophoblast represent both the primary barrier regulating transport between maternal and fetal vascular compartments and, also the principal source of steroid and peptide hormones produced by the human placenta. Syncytialization is driven by the endogenous retroviral envelope gene called syncytin-2 (ERVFRD-1). ERVFRD-1 is expressed on a subset of cytotrophoblast and acts through its receptor, MFSD2A, which is located on the syncytiotrophoblast cell surface (Lavialle et al., 2013). Another endogenous retroviral gene product referred to as syncytin-1 (ERVW-1) may contribute to the fusion process through its receptor, ASCT2 (Lavialle et al., 2013). The syncytins are also notable because they are regulated by GCM1 (Yu et al., 2002; Liang et al., 2010), a transcription factor pivotal to labyrinthine development in the mouse (Anson-Cartwright et al., 2000). Although, rodent and human syncytins are endogenous retroviral envelope genes that share overlapping functional properties, they evolved independently and are not orthologous genes (Dupressoir et al., 2012).

Final Thoughts

Trophoblast cells are an intriguing and unique cell lineage. The range of cellular functions originating from a relatively small number of trophoblast cell differentiation events is formidable. These specialized trophoblast cells single-handedly redirect maternal physiology to support the survival and growth of the fetus. A portion of this remarkable functionality is, undoubtedly, related to the extraordinary attributes of polyploid and multi-nucleated cells and their abilities to adapt to adversity (Oren-Suissa and Podbilewicz, 2010; Van de Peer et al., 2017). However, this is not the entire explanation because not all mammalian species possess these unique trophoblast cell populations (Wooding and Burton, 2008).

Gaps exist in understanding the precise molecular mechanisms controlling trophoblast cell development. These deficits arise, in part, from flawed approaches used to investigate trophoblast cells. It is important to appreciate that in vitro models are artificial paradigms and reflect cellular “potential” but not necessarily true physiological behavior. Nonetheless, in vitro systems can be powerful when combined with in vivo research strategies. Mouse and rat trophoblast stem cells can be effectively used to develop hypotheses regarding processes controlling trophoblast cell development. These hypotheses can then be tested in vivo using experimentally manipulated mouse or rat models. The rat is especially valuable in elucidating mechanisms controlling the invasive trophoblast cell lineage and uterine spiral artery remodeling. Limitations in current human trophoblast cell culture systems and ethical constraints with in vivo human trophoblast cell analyses present obstacles in understanding human trophoblast cell development. Efforts to identify and focus on “conserved” regulatory pathways are necessary to gain insights regarding human trophoblast cells. However, it is important to appreciate that conservation is not complete and species-specific elements characterize trophoblast cell biology and placentation.

In closing, trophoblast cell biology is integral to understanding placental development and pregnancy-related diseases. The process of trophoblast cell specialization is sensitive to intrinsic and extrinsic environmental challenges. Final construction of each placenta is unique and reflects a progression of adaptations responsive to signals emanating from both the mother and fetus. The nature of this dialog is dynamic and continually changes as pregnancy proceeds. Placental plasticity is a measure of the ability of trophoblast stem and progenitor cell populations to adapt and can be viewed as an important indicator of a healthy placenta. Placental dysfunction is linked to failures in the expansion and differentiation of trophoblast stem and progenitor cell populations and can originate from aberrations in communication with maternal and fetal environments or the consequence of intrinsic defects in the life history of trophoblast cells.

Introduction

Decidualization denotes the transformation of the endometrial stroma into the decidual matrix that supports embryo implantation and subsequent placenta formation. This process is foremost characterized by the differentiation of endometrial stromal cells (EnSCs) into secretory decidual cells (Gellersen and Brosens, 2014). Decidualization only occurs in species where the trophoblast breaches the luminal endometrial epithelium and invades maternal tissues. The depth of decidual transformation is determined by the degree of placental trophoblast invasion (Ramsey et al., 1976). In most mammals, decidualization is initiated upon embryo implantation. However, in a handful of species, including humans, Old World monkeys, some bats, elephant shrew, and spiny mouse, decidualization is “spontaneous,” meaning that it is initiated independently of an implanting embryo during the midluteal phase of each cycle (Emera et al., 2012). Once triggered, the decidual phenotype is strictly dependent on sustained progesterone signaling. In the absence of pregnancy, falling ovarian progesterone production triggers a cascade of inflammatory events in the decidualizing endometrium, which upon recruitment and activation of leucocytes becomes irrevocable and leads to partial tissue destruction, bleeding and menstrual shedding. Hence, spontaneous decidualization is inextricably linked to cyclic menstruation; and the term “decidua,” derived from the Latin verb “decidere” (meaning to fall off, to detach, or to die), aptly captures the nature of the process.

Although decidual transformation of EnSCs starts during the midluteal phase of the cycle, characteristic morphological changes are apparent only at the onset of the late-luteal phase, that is approximately 9–10 days after the postovulatory rise in circulating progesterone levels (Fig. 1). Decidualizing cells lose their fibroblastic appearance and become enlarged. They are further characterized by rounding of the nucleus, enlargement of the rough endoplasmic reticulum and Golgi apparatus, and accumulation of glycogen and lipid droplets (Gellersen and Brosens, 2014). Because of this expansion of the cellular secretory machinery, many genes that are constitutively expressed in epithelial cells are induced in EnSCs upon decidualization. The lag-period between ovulation and the onset of decidual process reflects the fact that transcriptional activation of decidual genes is strictly dependent on a sharp rise in intracellular production of the second messenger cyclic adenosine monophosphate (cyclic AMP) during the luteal phase. Cyclic AMP activates protein kinase A and induces the expression of decidual-specific transcription factors, such as the Forkhead box protein O1 (FOXO1), HOXA10 (Homeobox A10) and HOXA11, CCAAT-enhancer-binding proteins (C/EBPs). Once the decidual process is initiated, the liganded progesterone receptor (PGR) physically binds these core decidual-specific transcription factors, thus maintaining and amplifying the expression of differentiation genes, including *PRL* (coding prolactin) and *IGFBP1* (insulin-like growth factor-binding protein 1) (Gellersen and Brosens, 2014).

Typically, decidual transformation starts with EnSCs around the spiral arteries and underlying the luminal epithelium. Short- and long-range cytokines and morphogens then control the spatiotemporally progression of the decidual process, which in pregnancy encompasses the entire endometrium. It is important to note that decidualization of the stroma occurs in concert with profound changes in glandular gene expression and influx of immune cells, especially uterine natural killer (uNK) cells and, to

a lesser extent, macrophages. For an in-depth description of the molecular drivers of decidualization, we refer the reader to a recent review (Gellersen and Brosens, 2014). Here we focus on the emerging functions of the decidual process that enables the endometrium to transit from a cycling to a gestational tissue.

Ontogeny of Spontaneous Decidualization

Decidualization evolved in the stem lineage of Eutherian (placental) mammals. It bestows essential traits onto the uterus that enables controlled trophoblast invasion and confers maternal immune tolerance of the antigenically distinct fetus. These functions in turn underpin the formation of a hemochorial placenta and ensure effective maternal–fetal communication. Evolutionary, EnSCs acquired the ability to accommodate an invading conceptus upon genomic integration of transposable elements (TEs) enriched in *cis*-regulatory elements that co-opted specific transcription factors to drive decidual gene expression (Lynch et al., 2011).

As aforementioned, decidualization is triggered by the implanting embryo in all but menstruating mammals. However, the ability of human EnSCs to decidualize in response to maternal cues is not innate but acquired (Brosens et al., 2017). For example, the fetal human endometrium is exposed during gestation to progressively rising plasma concentrations of unbound estrogens and progesterone, which at birth are several-fold higher when compared to the maternal circulation. Circulating progesterone levels drop very rapidly in the newborn yet overt vaginal bleeding is uncommon, affecting approximately 5% of neonates. Further, an autopsy study on 169 newborn girls demonstrated inactive or weakly proliferative endometrium in 68% of term babies and secretory glandular changes in 27% of newborns. Evidence of decidualization of the stroma or menstrual changes was observed in only 5% of cases.

The lack of neonatal menstruation in most newborns suggests that endometrium only acquires the ability to decidualize around the menarche. The process that renders the endometrium permissive to decidualization is as yet unclear, although there are a number of pointers. In nonmenstruating mammals, decidualization is readily triggered in hormonally primed animals by exogenous stress signals, including endometrial scratching or exposure of the uterine cavity to oil. An emerging line of thought is that rapid estrogen-dependent growth during the follicular phase causes replicative exhaustion of a subpopulation of endometrial cells, which then produce an endogenous stress signal in response to acute senescence during the midluteal phase (Brosens et al., 2017). Cellular senescence is characterized by permanent cell cycle exit and secretion of a host of inflammatory mediators, commonly referred to as senescence-associated secretory phenotype. Several lines of circumstantial evidence support this hypothesis including the fact that the menarche is preceded by a prolonged rise in estrogen levels and sustained uterine growth. Further, telomere lengths of endometrial cells are shortest during the midluteal phase in the cycle, indicative of replication stress. Furthermore, permanent cell cycle exit at G0/G1 during the midluteal phase is a prerequisite not only for cellular senescence but also for terminal differentiation of EnSCs into decidual cells. Clinically, it is well established clinically that rapid estrogen-dependent endometrial growth during the proliferative phase is necessary for successful embryo implantation (Brosens et al., 2017).

Decidualization: A Multistep Process

Decidualization is not an all or nothing process as is often assumed. Instead, differentiating EnSCs transit through distinct phases (Fig. 2) each of which bestows unique functions onto the endometrium that are essential for successful implantation (Gellersen and Brosens, 2014).

Analysis of EnSCs in culture demonstrated that the decidual pathway starts with a burst of reactive oxygen species (ROS) and secretion of a host of chemokines and other inflammatory mediators (Al-Sabbagh et al., 2011; Lucas et al., 2016; Salker et al., 2012), many of which are involved in recruitment and activation of innate immune cells. Feedback pathways ensure that the inflammatory decidual response is self-limiting, lasting between 2 and 4 days. The second decidual phase is characterized by simultaneous downregulation of various chemokines and inflammatory mediators (Al-Sabbagh et al., 2011; Lucas et al., 2016). During this anti-inflammatory phase, decidual cells are increasingly connected and form a matrix through gap and tight junctions. In concert, decidual cells express high levels of 11 β -hydroxysteroid dehydrogenase type 1, an enzyme that converts inert cortisone to active cortisol (Kuroda et al., 2013). This cortisol gradient in the decidua likely contributes to the protection of the invading allogeneic fetal trophoblast against a maternal immune response. Further, by silencing chemokine expression, decidual cells actively prevent effector T cells from entering the feto-maternal interface (Erlebacher, 2013). The third and final phase involves the resolution of the decidual phenotype, triggered in a nonconception cycle by falling progesterone levels. In pregnancy, senescence is thought to drive decidual inflammation. During this phase, secretion of inflammatory factors and matrix metalloproteinases sets in motion a cascade of events that either results in menstruation or contributes to the onset of parturition (Gellersen and Brosens, 2014). In recent years, new insights into the functional importance of this triphasic decidual pathway have emerged.

The Window of Implantation

A limited implantation window is critical as it synchronizes two parallel but initially independent processes: embryo development and endometrial maturation. In mice, a single endocrine signal not only functionally switches a progesterone-primed, prereceptive endometrium to a receptive state but also activates the “dormant” preimplantation embryo. This obligatory maternal implantation

Fig. 2 Schematic diagram of the distinct phases upon spontaneous decidualization, rendering the endometrium first receptive to embryo implantation and selective for embryos of different developmental potential. For full details, see text.

signal consists of a transient rise in postovulatory estradiol production. By contrast, there is no evidence that the midluteal implantation window in human endometrium is controlled by a nidatory estradiol surge, perhaps reflecting that synchronized implantation of multiple human embryos is neither required nor desirable. Instead, compelling experimental evidence suggests that the initial autoinflammatory decidual response renders the endometrium receptivity for embryo implantation. For example, exposure of the mouse uterus to proinflammatory secretome of decidualizing human EnSCs induces the expression of evolutionarily conserved implantation genes, including *Wnt4*, leukemia inhibitory factor (*Lif*), and bone morphogenetic protein 2 (*Bmp2*), and enables efficient implantation of *in vitro* cultured mouse blastocysts (Salker et al., 2012). Furthermore, human blastocysts degrade when cultured in medium conditioned by undifferentiated EnSCs but not decidual cells, suggesting that the endometrium is actively embryotoxic prior to decidualization (Peter Durairaj et al., 2017).

Embryo Biosensing and Selection

Human embryos are characterized by intrinsic genomic instability (McCoy et al., 2015). Meiotic chromosomal aneuploidies correlate strongly with maternal age and disproportionally affect smaller maternal chromosomes. By contrast, chaotic cell divisions caused by spindle abnormalities in early cleavage stage embryos result in complex mitotic aneuploidies that are independent of maternal age, frequently involve larger chromosomes, and are not biased towards either maternal or paternal homologs. As a consequence of mitotic disjunction during the cleavage stages, most—if not all—human preimplantation embryos harbor aneuploid blastomeres. While some chromosomal errors may lead to early embryonic arrest, complex mosaic aneuploidies remain prevalent at the blastocyst stage.

The human endometrium is adapted to deal with this diversity in embryo quality. In fact, the coupling of spontaneous decidualization to menstrual shedding could be viewed as an ingenious solution to deal with chaotic and potentially highly invasive blastocysts. First, with menstruation being the default position, an effective and safe “disposal system” for aberrant embryos is built into the cycle. Second, a significant lag-period exists between implantation and sufficient progesterone production by the emerging placenta. This lag-period makes it incumbent on the implanting embryo to produce sufficient “fitness” signals, such as human chorionic gonadotropin (hCG), to avoid corpus luteum failure and inevitable rejection. Furthermore, decidual cells have emerged as exquisite biosensors of embryo quality and mount a tailored response to an implanting blastocyst that either supports further development or results in a stress response that facilitates early disposal (Brosens et al., 2014).

Different experimental models have highlighted the particular aptness of decidualizing cells in sensing poor quality human embryos. In coculture, decidualizing EnSCs respond to a developmentally compromised blastocyst by silencing the secretion of

multiple implantation factors, including interleukin-1 β and Heparin-binding EGF-like growth factor (HB-EGF). By contrast, undifferentiated EnSCs appear impervious to embryonic signals, irrespective of developmental potential. Furthermore, genome-wide expression profiling revealed a dramatic up-regulation of implantation and metabolic genes in mouse uteri transiently exposed to spent medium of human IVF embryos that resulted in ongoing pregnancies following transfer. By contrast, culture medium conditioned by low-quality human embryos triggered a stress response in the mouse uterus akin to the response observed in primary decidualizing EnSCs (Brosens et al., 2014).

When extrapolated to the *in vivo* situation, these observations strongly suggest that human embryos are subjected to both positive and negative selection pressures at implantation. Efficient biosensing and negative selection of poor quality embryos at implantation results in preclinical attrition. However, lack of negative selection increases the risk of implantation of developmentally compromised embryos and early pregnancy loss. Similarly, failure of positive selection results in high-quality embryos developing in an unsupportive or hostile maternal environment, which arguably predisposes for fetal miscarriage. The clinical hallmark of persistent lack of embryo selection at implantation is superfertility, defined by a mean time to pregnancy of three cycles or less. The estimated incidence of superfertility in the general population is 3%. By contrast, 40% of patients suffering recurrent pregnancy loss (RPL), defined here as three consecutive miscarriages, are reportedly superfertile. The incidence is even higher in women who experienced five or more miscarriages (Salker et al., 2010).

The mechanism that imparts responsiveness of decidual cells to soluble signals from developmentally competent and incompetent embryos is poorly understood. Nevertheless, *HSPA8* has been identified as the most downregulated decidual gene in differentiating EnSC cultures exposed to the secretome of developmentally impaired human embryos (Brosens et al., 2014). *HSPA8* encodes heat shock 70 kDa protein 8 (HSC70), a key regulator of cellular protein homeostasis. HSC70 levels increase upon decidualization in parallel with expansion of the endoplasmic reticulum that drives the secretory phenotype of differentiating EnSCs. Hence, the importance of this molecular chaperone increases as decidual cells expand their secretory machinery, which may explain why undifferentiated endometrial fibroblasts are not bequeathed with a biosensor function.

Decidual Resolution and Menstruation

Falling progesterone levels in a nonconception cycle reactivates the inflammatory decidual phenotype, harbinger of menstrual shedding of the superficial endometrial layer. Women now experience in excess of 400 cycles of menstrual shedding and scar-free regeneration during the reproductive years. However, there are two consequences of cycling endometrium shedding and regeneration that tend to be overlooked. First, cell turnover in cycling endometrium is very high. Not surprisingly, the human endometrium is rich in glandular progenitor cells and mesenchymal stem-like cells (MSC), which reside not only in the basal endometrium but also in a perivascular niche around the spiral arteries. Endometrial MSC are identified by specific cell surface markers, such as Sushi Domain containing 2 (SUSD2) or coexpression of CD146 and platelet-derived growth factor receptor beta (PDGFR β) (Gellersen and Brosens, 2014). Apart from MSC, the endometrial stromal compartment consists of other distinct subpopulations that are defined either by the stage of lineage commitment (e.g., transit amplifying cells, mature progeny, and presenescent cells) or topology (e.g., perivascular EnSCs). Growing evidence indicates that response to decidualogenic signals differs profoundly between subpopulations of EnSCs. For example, perivascular EnSCs are relatively quiescent in an undifferentiated state but become a dominant source of chemokines and cytokines upon decidualization (Murakami et al., 2014). Thus, the spatiotemporal control of decidual response is governed by distinct responses in various EnSC subpopulations. A second important consequence of menstruation is that spontaneous decidualization is an iterative process. As the abundance of different EnSC subpopulations likely fluctuates from cycle to cycle, the quality of the decidual response may equally vary in different cycles. Consequently, cyclic menstruation and renewal renders the endometrium intrinsically dynamic and arguably capable of adapting in response to reproductive failure.

Decidual Cells: Instructors of Local Immune Cells

As aforementioned, spontaneous decidualization of EnSCs during the luteal phase of the cycle occurs in parallel with recruitment of innate immune cells, predominantly CD56^{bright}/CD16⁻ uNK cells. During the late-luteal phase, as many as 30%–50% of cells in the endometrial stroma are uNK cells. Compared to their circulating (CD56^{dim}/CD16⁺) counterparts, uNK are less cytotoxic but more proangiogenic; and exert an evolutionarily conserved role in orchestrating vascular adaptation and trophoblast invasion during pregnancy.

Decidual cells play a pivotal role in instructing uNK cells; meaning that they provide the necessary cues that enable these cells to carry out their specialist functions in pregnancy. For example, conditioned medium from decidual cells supplemented with interleukin-15 and stem cell factor convert peripheral NK cells into uNK-like cells. Coculture with decidual stromal cells also convert CD34⁺ hematopoietic precursors into phenotypic uNK cells. Further, when injected into immunocompromised pregnant mice, induced uNK-like cells migrate to the uterus and improve placental perfusion. Thus, decidual cells not only protect the semiallogenic conceptus against a maternal immune response through local cortisol production and by actively excluding T-cells, they are also instrumental in adapting innate immune cells for pregnancy (Brosens et al., 2017).

Decidual Autonomy in Early Pregnancy

In early pregnancy, the conceptus is embedded in a matrix of decidual cells. As the process of interstitial and endovascular trophoblast invasion commences, the embryo–maternal interface is increasingly subjected to intense tissue remodeling and exposed to profound changes/fluctuations in oxygen tension associated with vascular remodeling. Decidual cells are programmed to resist a range of environmental stress signals, thus ensuring survival of the conceptus. Several molecular mechanisms underpin this quasiautonomous state of decidua prior to the onset of placental perfusion around 10 weeks of pregnancy (Fig. 3).

Cessation of Circadian Rhythms

An early event that signals autonomy of decidualizing EnSCs is cessation of circadian gene expression. Circadian oscillations are predicated on transcriptional–translational feedback loops that balance the activities of the transcriptional activators CLOCK and BMAL1 and repressors encoded by *PER* and *CRY* genes. An early event in the decidual pathway is loss of the clock protein Period 2 (PER2), which in turn silences circadian gene expression in differentiating EnSCs (Muter et al., 2015). As the implanting conceptus is also aperiodic, cessation of circadian oscillations in surrounding decidual cells is arguably essential for optimal embryo–maternal interactions. However, PER2 differs from other core clock proteins in that it exhibits several structural features of steroid receptor coregulators. Further, PER2 knockdown arrests EnSCs at G2/M and results in a grossly disorganized decidual response. Thus, regulation of PER2 expression across the cycle synchronizes endometrial proliferation with initiation of aperiodic decidual gene expression. The importance of transition is underscored by the observation that endometrial *PER2* transcript levels in the midluteal phase of the cycle correlate inversely with the number of previous miscarriages in RPL patients (Muter et al., 2015).

Oxidative Stress Resistance

ROS, including superoxide anion radical, hydrogen peroxide, and the hydroxyl radical, are highly reactive, diffusible, and ubiquitous molecules that are generated as inevitable byproducts of aerobic respiration and metabolism. Mammalian cells possess multiple mechanisms to remove ROS, including endogenous enzymatic and dietary nonenzymatic antioxidants. Detoxification of superoxide by superoxide dismutase enzymes converts it to hydrogen peroxide. Catalase and glutathione peroxidase further degrade hydrogen peroxide to produce water as the end product. Physiological levels of ROS are required to ensure proper functioning of different biological pathways and to maintain tissue homeostasis. However, excessive levels of ROS cause irreversible damage to DNA, proteins, and lipids, ultimately resulting in cell death.

Decidual cells are remarkably resistant to oxidative cell death compared to their undifferentiated progenitor cells (Gellersen and Brosens, 2014). This resistance is partly accounted for by the induction of various free radical scavengers, most notably superoxide dismutase 2, monoamine oxidases A and B, thioredoxin, glutaredoxin, and peroxiredoxin. Several genes coding free radical

Fig. 3 Illustration of molecular mechanisms of decidual autonomy in early pregnancy. For full details, see text. (1) Cessation of circadian rhythms, (2) oxidative stress resistance, (3) uncoupling of stress signaling and SUMOylation, and (4) silencing of phospholipase C signaling. scavengers are transcriptionally controlled by FOXO1, a core decidual transcription factor. However, a second mechanism contributes to the exceptional ROS resistance in decidual cells. Exposure of undifferentiated EnSCs to exogenous free radicals rapidly activates the c-Jun NH-terminal kinase (JNK) stress signaling pathway and upregulates another forkhead protein, FOXO3a, which in turn triggers cell death. However, decidual cells strongly upregulate mitogen-activated protein (MAP) kinase phosphatase-1 (MKP-1), which not only silences the JNK pathway but also inhibits FOXO3a expression. Hence, while undifferentiated HESCs are programmed to self-destruct in response to oxidative stress signals, this mechanism is firmly disabled upon differentiation into decidual cells (Gellersen and Brosens, 2014).

Uncoupling of Stress Signaling and SUMOylation

A striking adaptation in decidual cells involves the small ubiquitin related modifier (SUMO) conjugation/deconjugation pathway. SUMOylation, an important posttranslational protein modification that affects a large number of substrates, is catalyzed through a sequence of enzymatic reactions. This reversible posttranslational protein modification regulates numerous cellular processes, including cell signaling, nuclear transport, transcription, and DNA replication and repair. Nuclear receptors, including PGR, are important SUMO targets. The transcriptional activity of PGR in response to progesterone binding is strongly repressed upon SUMOylation. Interestingly, decidualization is associated with global cellular hypoSUMOylation, effected by altered expression of SUMO-specific ligases and proteases. Various stress signals convert on the SUMO pathway, including ROS, hypoxia, heat shock, and genotoxic stress. However, induction of MKP1 and silencing of the JNK pathway ensure that decidual cells do not exhibit a hyperSUMOylation response when exposed to exogenous stress signals (Gellersen and Brosens, 2014). Importantly, this means that progesterone signaling is unimpeded in the decidua under the oxidative stress conditions imposed by pregnancy.

Silencing of Phospholipase C Signaling

Further decidual autonomy is achieved via induction of phospholipase C (PLC)-related catalytically inactive protein 1 (PRIP-1). PRIP-1 is a progesterone-inducible scaffold protein that uncouples PLC activation downstream of G_q -protein-coupled receptors from intracellular Ca^{2+} release by attenuating inositol trisphosphate (IP3) signaling (Muter et al., 2016). As many external signals are transduced by G_q -protein-coupled receptors, strong induction PRIP-1 is a remarkably simple solution to ensure decidual autonomy. Furthermore, by chelating IP3, PRIP-1 also limits Ca^{2+} release from the expanding endoplasmic reticulum, thereby safeguarding decidual cells against excessive Ca^{2+} accumulation in the mitochondrial matrix, permeabilization of the mitochondrial outer membrane, and cell death caused by leakage of apoptosis factors from the intermembrane space.

Clinical Perspective

Failure of the endometrium to mount a decidual response inevitably leads to implantation failure whereas a prolonged and disordered autoinflammatory decidual response is linked to out-of-phase implantation, impaired embryo biosensing, and RPL. Clinically, implantation failure is the rate-limiting step in assisted reproductive technologies whereas miscarriage is the most common complication of pregnancy. The incidence of clinical miscarriage after 6 weeks of pregnancy is approximately 15%. When preclinical losses are taken in account, the incidence of early pregnancy attrition is estimated to be between 30% and 50%. Numerous gene ablation studies in mice have identified key signals, pathways, and downstream transcription factors that are indispensable for decidualization (Gellersen and Brosens, 2014). However, clinical translation of this information into either new treatment or endometrial biomarkers predictive of reproductive failure has so far be elusive.

So, what are the roadblocks? An obvious hurdle is that human blastocysts, unlike their murine counterparts, are chromosomally diverse. Because of intrinsic mosaicism, it remains difficult, if not impossible, to predict accurately the developmental potential of an individual embryo, even following preimplantation genetic screening. Consequently, it is often not possible to ascertain retrospectively if implantation failure or early pregnancy loss was caused by an embryonic, a maternal factor, or a combination. In general, the likelihood of an underlying endometrial defect compromising nidation or development of a competent embryo increases with each additional failure. Another hurdle, perhaps less appreciated, is that spontaneous decidualization and cyclic menstruation renders the endometrium intrinsically dynamic (Lucas et al., 2016). In other words, analysis of the endometrium in a given cycle may not necessarily be predictive of implantation competence in a subsequent cycle.

Yet, these perceived hurdles—embryo diversity and endometrial plasticity—also belie the clinical observation that the cumulative live birth rate for most women is high, even after multiple implantation failures or miscarriages. For example, several randomized double-blind placebo control studies reported live births rates of 65% or more in patients with three consecutive miscarriages who were assigned to the placebo group. Even after five consecutive miscarriages, the likelihood of a live birth in a subsequent pregnancy remains in excess of 50%. Similar high cumulative live birth rates have been reported following implantation failure in IVF. Hence, it is as paramount to understand the mechanisms that enable a successful pregnancy to occur after multiple failures as it is to define the primary cause of reproductive failure. The discovery of specific endometrial defects associated with RPL, such as stem cell deficiency (Lucas et al., 2016), is opening up the possibility of prepregnancy screening of women at risk of reproductive failure. Effective interventions, however, will require a more in-depth understanding of the mechanisms that control endometrial homeostasis, and by extension the decidual pathway, from cycle to cycle.

Human Placentation

The Human Placenta

Already the early Egyptians have recognized and venerated the human placenta. In ancient Greece, Diogenes of Apollonia (about 480 BCE) was the first to describe the placenta as being responsible for fetal nutrition. Only during Renaissance times (1559) Realdus Columbus started to use the term placenta, which was taken from the Latin root for a flat cake.

Development of the Human Placenta

Prelacunar Phase (Days 5–8 after Fertilization)

The trophoblast is the first cell line that differentiates in an embryo. It develops at day 5 after fertilization (day 5 post conception, p.c.), leading to the formation of the blastocyst. The trophoblast cells of the blastocyst organize themselves as a ball-shaped cover (*trophectoderm*), surrounding the blastocyst cavity and the inner cell mass (*embryoblast*). Later during pregnancy, the trophoblast only resides within the placenta, while the cells of the embryoblast will form the whole embryo proper plus specific tissues within the placenta.

The blastocyst adheres to the uterine luminal epithelium at day 6–7 p.c., inducing further differentiation of the trophoblast. Those trophoblast cells in direct contact with the uterine epithelium fuse with each other and develop into the first multinucleated *syncytiotrophoblast*. In the human, the syncytiotrophoblast seems to be the layer that enables penetration of the uterine epithelium and invasion of the embryo into the decidual connective tissues.

The blastocyst has completely passed the uterine epithelium at day 7–8 p.c. The trophoblast grows massively during this process, becomes multi-layered and completely surrounds the embryo that does not come into direct contact with maternal tissues. The multinucleated syncytiotrophoblast at the outside of the placenta directly contacts maternal cells and tissues, while the mononucleated *cytotrophoblasts* face towards the embryo.

All the above stages and phases of differentiation and development occur prior to the development of fluid-filled spaces within the syncytiotrophoblast. This is why this phase is termed *prelacunar phase* (Benirschke et al., 2006).

Lacunar Phase (Days 8–12 after Fertilization)

The syncytiotrophoblast forms a growing number of fluid-filled spaces, starting around day 8–9 p.c. This defines the start of the *lacunar phase* (Benirschke et al., 2006). Due to flowing together of these spaces a large single fluid-filled space develops, the *intervillous space*. Between the trophoblast on the embryonic side and the trophoblast facing maternal tissues this fluid-space develops, only leaving a number of trophoblast branches (trabeculae) bridging the two sides of trophoblast.

At the end of the lacunar phase, at day 12 p.c., the embryo has invaded deeper into the uterine wall and is now completely embedded into decidual tissues. At that time the embryo adds a new tissue layer of mesenchymal cells (*extra-embryonic mesoderm*) underneath the two types of trophoblast, the mononucleated cytotrophoblasts and the multinucleated syncytiotrophoblast.

All the above processes of development have subdivided the placenta into different compartments:

1. The cytotrophoblasts at the embryonic side plus the mesoderm cells will develop into the *chorionic plate*.
2. The trabeculae will develop into *anchoring villi* that adhere the placenta proper to the uterine wall.
3. Side branches of the trabeculae will develop into *floating villi*.
4. The fluid-filled spaces villi develop into the intervillous space; the latter will be the chamber for maternal blood during hemotrophic nutrition of the fetus.
5. The part of the trophoblast at the maternal side of the placenta plus cellular and acellular components of the decidua will develop into the *basal plate*.

Early Villous Phase (Days 13–28 after Fertilization)

During this phase, first placental villi develop as the precursors of the specific placental villi later in pregnancy (Benirschke et al., 2006). Proliferation of cytotrophoblasts at the embryonic side of the placenta pushes a set of these cells into the syncytial trabeculae. The latter structures are finally fully penetrated by mononucleated cells that reach the maternal side of the syncytiotrophoblast at day 14 p.c. Further proliferation of cytotrophoblasts within the trabeculae leads to the development of syncytial protrusions and finally side branches filled with cytotrophoblasts (*primary villi*, day 13 p.c.).

Mesenchymal cells of the extra-embryonic mesoderm follow the cytotrophoblasts and penetrate the trabeculae as well as the primary villi, resulting in the generation of *secondary villi* with two trophoblast layers outside and a mesenchymal core.

Finally, at about day 18–20 p.c., new vessels form based on hemangioblastic precursor cells within the villous mesenchyme (*vascularization*) (Demir et al., 2004). These first placental vessels give rise to the development of *tertiary villi* (Fig. 1).

Due to the fact that placental villi develop from single trabeculae, they are organized in *villous trees* (with the trabecula becoming the stem villus of the tree). These villous trees become the major spherical units of the placenta and are termed lobules or *placentomes*. The side branches of the trabeculae, the placental villi, continuously branch resulting in multiple branching sites from the stem villus to the outermost floating and freely ending villi in the intervillous space.

Villous Phase (Day 28 after Fertilization to End of Pregnancy)

Growth of placental villi occurs following a uniform principle. On the surface of larger villi the syncytiotrophoblast protrudes and forms *syncytial sprouts* (Fig. 1). Underneath these sprouts, increased proliferation of cytotrophoblasts pushed the daughter cells into the sprouts (primary villi). Then mesenchymal cells follow (secondary villi) and finally blood vessels reach the villi (tertiary villi) starting from already existing vessels in the larger villus (*angiogenesis*) (Benirschke et al., 2006).

This uniform way of villous development results in a general layout of such villi with a specific set of layers, cells and tissues.

Villous layers, cells and tissues

Villous cytotrophoblast

Morphologically, *villous cytotrophoblasts* are characterized by their roundish shape in histological sections (Fig. 1). Their nuclei are large and present only minor amounts of heterochromatin. During the first trimester a complete layer of villous trophoblasts can be found underneath the syncytiotrophoblast (Benirschke et al., 2006). A basement membrane is separating this layer from the villous stroma. Throughout pregnancy the villous core is growing faster than this layer of cells resulting in a seemingly reduction of cells. At term the villous cytotrophoblasts can be found as single cells lying underneath the syncytiotrophoblast, a complete layer is no longer present.

The continuous increase in the number of villous cytotrophoblasts during pregnancy can be seen from cell numbers over gestation: about 1×10^9 cells at 13–16 weeks and about 6×10^9 cells at 37–41 weeks (Benirschke et al., 2006). The rate between proliferation of villous cytotrophoblast and syncytial fusion with the overlying syncytiotrophoblast remains quite constant over gestation. The relation between villous cytotrophoblast nuclei and syncytial nuclei is 1:9, irrespective whether this is counted at 13–16 weeks of gestation or at 37–41 weeks (Mayhew et al., 1999).

Villous cytotrophoblasts do not direct contact to maternal blood. If focal damage of the syncytiotrophoblast occurs, the hole is filled with *fibrin-type fibrinoid* (a maternal blood clot product) covering the exposed cytotrophoblasts (Benirschke et al., 2006).

Syncytiotrophoblast

As the outermost layer of all villi, the syncytiotrophoblast covers all placental villi as one single layer covering all villi of a single placenta. This layer is a true syncytium, developed and maintained by fusion of mononucleated cells and without any lateral cell borders (Benirschke et al., 2006). The syncytiotrophoblast is easily identifiable during the first half of pregnancy (Fig. 1) and is characterized by a continuous row of nuclei. During the second half of pregnancy the syncytiotrophoblast becomes thinner to reduce the diffusion distance between maternal and fetal blood. Also the syncytial nuclei are now ordered in groups at specific sites to allow maximal thinning of the syncytiotrophoblast at sites of direct contact of placental blood vessels with the trophoblast layer.

As maintenance and growth of the syncytiotrophoblast are based on syncytial fusion with the underlying cytotrophoblasts, syncytial nuclei are introduced into this layer by fusion, show different levels of aging and do no longer show any signs of

Fig. 1 Cross section through a mesenchymal villus at 5–6 weeks of gestation. This villus comprises all the typical tissues and cells characteristic for a first trimester villus: a cover by the syncytiotrophoblast, a complete layer of villous cytotrophoblasts, and a villous stroma with mesenchymal cells, Hofbauer cells and blood vessels. On the upper right a tangential section through a syncytial sprout can be seen pointing to further growth of the villous trees.

proliferative activity. Directly after fusion the syncytial nuclei exhibit a large and ovoid shape, then during the 3–4 weeks of staying within the syncytiotrophoblast they become smaller and denser. Finally, they show clear signs of late apoptosis with envelope convolution, increased packing density and increased heterochromatinization (Huppertz, 2010). The aged nuclei accumulate at specific sites (often at the tips of villi), are packed into protrusions of the syncytial apical membrane (*syncytial knots*) and are released into the maternal circulation as apoptotic corpuscular structures (Benirschke et al., 2006; Huppertz, 2010). Interestingly, signs of late apoptosis are extremely rare in the villous cytotrophoblast but may well occur in those cytotrophoblasts that fail to undergo syncytial fusion (Longtine et al., 2012).

The syncytiotrophoblast is the site with the highest metabolic and endocrine activity in the placenta. The main function of this layer is the materno-fetal (and feto-maternal) transfer and its control, including (Benirschke et al., 2006):

- Active transport of amino acids and electrolytes such as sodium and calcium,
- Facilitated transport of glucose,
- Diffusion of water and gases,

as well as

- Synthesis of a variety of hormones such as β -hCG (beta-subunit of human chorionic gonadotropin) and
- Catabolism and resynthesis of proteins and lipids.

Villous trophoblast turnover

Each epithelium shows proliferation at the basal side and extrusion of aged material at the apical side. Also the villous trophoblast exhibits this phenomenon of continuous turnover, which comprises the following steps (Huppertz et al., 1998; Huppertz, 2010):

- Proliferation of a subset of cytotrophoblast progenitor cells.
- Differentiation of post-proliferative mononucleated daughter cytotrophoblasts within 2–3 days.
- Syncytial fusion of finally differentiated cytotrophoblasts with the overlying syncytiotrophoblast.
- Further differentiation and maturation of cellular components and organelles within the syncytiotrophoblast, including nuclei (3–4 weeks).
- Aging and late apoptosis at specific sites of the syncytiotrophoblast.
- Packing of aged material into syncytial knots, mostly known for aged nuclei.
- Syncytial knots are extruded into the maternal circulation (Huppertz et al., 1998; Benirschke et al., 2006).

During gestation, a large number of such syncytial knots is detached from the syncytiotrophoblast and released into the maternal circulation. In late gestation up to 150,000 such corpuscular structures or 2–3 g of trophoblast material have been estimated to enter the maternal circulation each day (Huppertz et al., 1998; Benirschke et al., 2006). Since most of these multinucleated structures become lodged in the capillary bed of the lungs, they are extremely rare in arterial or peripheral venous blood of pregnant women.

Placental mesenchyme

The mesenchymal stroma within the core of placental villi (Fig. 1) is composed of a population of fixed and moving connective tissue cells including (Benirschke et al., 2006):

- Mesenchymal cells (Fig. 1) and fibroblasts in different stages of differentiation up to myofibroblasts.
- Placental macrophages (*Hofbauer cells*). Placental macrophages (Fig. 1) differentiate from progenitor cells within the mesenchyme of placental villi even prior to onset of blood flow between embryo and placenta. Afterwards, placental macrophages are also recruited from blood-derived monocytes.
- Placental vessels with smooth muscle cells and endothelial cells including arteries, veins, capillaries and sinusoids. During the first trimester of pregnancy, placental vessels (Fig. 1) are not surrounded by a basement membrane, which only develops afterwards. The endothelium of placental capillaries acts as passive filter and reduces the intercellular transfer of molecules (Eaton et al., 1993).

Villous types

During pregnancy five specific types of villi develop and can be distinguished based on their diameter/perimeter, stromal characteristics, vessel structures and functions (Benirschke et al., 2006; Baergen, 2011) (Fig. 2). Each stage of pregnancy can be defined by a specific subset of villous types.

Mesenchymal villi

Mesenchymal villi are the first type of villi that develops as soon as the first tertiary villi have evolved at around day 20 p.c. Hence, mesenchymal villi are the forerunners of all other villous types. During the first and second trimester mesenchymal villi differentiate into immature intermediate villi, while during the third trimester they directly differentiate into stem villi. Early during pregnancy mesenchymal villi are the dominant villous type, while at term only about 1% of the villous volume can be attributed to mesenchymal villi.

Fig. 2 The five villous types in a human placenta: (A) mesenchymal villus, (B) immature intermediate villus, (C) stem villus, (D) terminal villus, and (E) mature intermediate villus. (F) Gives an overview of a cross section through a term placenta with centrally located stem villi surrounded by mature intermediate villi and terminal villi.

Mesenchymal villi have diameters between 40 and 80 μm and show two-layered villous trophoblast coverage with the syncytiotrophoblast and a clear layer of villous cytotrophoblast (Fig. 2A). Their stromal core is characterized by only few fibers such as collagen type I, few fibroblasts and Hofbauer cells and first small vessels. At the same time the core is full of undifferentiated mesenchymal cells. Mesenchymal villi are the villous type with the highest proliferation rates, mostly due to massive proliferation of mesenchymal cells and villous cytotrophoblasts.

Immature intermediate villi

Immature intermediate villi, the first villous type differentiating from mesenchymal villi, start to show up starting at about week 8 of gestation (post menstruation, p.m.). This villous type is prevailing between weeks 14–20, while at term only about 5% of the villous volume can be attributed to immature intermediate villi. This villous type is much larger than mesenchymal villi with diameters between 100 and 300 μm . Their stromal core shows a loose reticular connective tissue with little extracellular matrix, small blood vessels and large numbers of Hofbauer cells. The specific characteristic of immature intermediate villi is the presence of stromal channels (Benirschke et al., 2006) (Fig. 2B). These channels are fluid-filled spaces along the roll axis of the villi and do not have any known connection to blood vessels. They are surrounded by fibroblasts but lack any relation to endothelial cells. Hofbauer cells are present in these channels and hence can easily be identified in these villi.

Stem villi

Stem villi develop from further differentiation of immature intermediate villi or directly differentiate from mesenchymal villi. Stem villi show up at about week 18–20 p.m. and are the largest villi with diameters of 100 μm to some millimeters. Due to their size about 20%–25% of the villous volume at term can be attributed to this villous type. Stem villi function as mechanical stabilization of the whole villous tree, similar to the trunk of a tree.

The villous trophoblast of stem villi is quite thin with low numbers of villous cytotrophoblasts. The villous stroma is filled with only few fibroblasts and Hofbauer cells but lots of fibers such as collagen type I and other matrix components to stabilize this type of

villi. The large stem villi (Fig. 2C) are characterized by two centrally located vessels (artery and vein) surrounded by a system of extravascular contractile cells that locally regulate vessel diameters in the absence of nerve cells in the placenta.

Mature intermediate villi

At the beginning of the third trimester (about week 24 p.m.) mesenchymal villi differentiate into *mature intermediate villi*, the latter with diameters between 80 and 120 μm . At term about 25% of the villous volume can be attributed to mature intermediate villi. This villous type displays long and slender villi, a loose connective tissue, often marginal small vessels and some terminal arterioles and venules (Fig. 2E). Mature intermediate villi serve as source for terminal villi and connect terminal villi with stem villi.

Terminal villi

Terminal villi are the last type of villi that develops during pregnancy appearing at about week 27 of gestation. This villous type does not differentiate from a forerunner but rather develops from protrusions of mature intermediate villi. Within these intermediate villi an increased longitudinal growth of vessels results in protrusions of vessels covered by villous trophoblast, terminal villi (Fig. 2D).

The function of terminal villi is the direct exchange between mother and fetus across the placental barrier. The placental barrier is the tissues between maternal and fetal blood that need to be crossed to enable exchange. This barrier comprises the syncytiotrophoblast, sometimes also villous cytotrophoblasts, the trophoblastic basement membrane, sometimes villous stroma, the endothelial basement membrane and endothelial cells of the placental blood vessels. In a best-case scenario the placental barrier consists of the syncytiotrophoblast, the merged basement membranes of trophoblast and endothelium and the endothelium (termed *vasculosyncytial membrane*). Here, the thickness of the barrier may decrease down to 0.5–2 μm .

Terminal villi show a length of about 200 μm with diameters between 50 and 100 μm . In a term placenta about 40% of villous volume can be attributed to this type of villi. Capillaries within terminal villi often show extension of their diameters and are referred to as sinusoids. Due to their function as exchange villi, sometimes more than 50% of the stromal cross section is dominated by vessels (capillaries and sinusoids).

Interestingly, the number of terminal villi follows their microenvironment within the placenta. In cases with maternal hypoxia (chronic anemia or pregnancy at high altitude) less oxygen reaches the placenta. The third trimester placenta senses and reacts on this altered environment by increasing the number of terminal villi to increase exchange surface area. On the other hand, cases with growth restricted babies and reduced blood flow in the umbilical arteries leads to an increase in placental oxygen concentrations (Sibley et al., 2002) followed by regression and thus decreased numbers of terminal villi.

Extravillous Trophoblast

Cytotrophoblasts that penetrate the trabeculae finally reach the decidual tissues where they come into direct contact with maternal cells. The mesenchymal cells that subsequently penetrate the trabeculae, however, do not reach maternal tissues (Benirschke et al., 2006). This difference in depth of penetration results in the formation of multiple layers of cytotrophoblasts at the tips of the trabeculae, which then turn into anchoring villi. These trophoblast layers are referred to as *trophoblastic cell columns* (Benirschke et al., 2006) (Fig. 3). Within the cell columns only those cytotrophoblasts remain in a proliferative state that are in direct contact to the basement membrane separating trophoblasts from the mesenchymal core of the anchoring villi. Their proliferative pressure pushes cytotrophoblasts down the columns where they finally reach and start actively invading maternal tissues.

Fig. 3 Trophoblast cell columns. (A) The invasive front of a placenta at 15 weeks of gestation. Multiple cell columns (arrows) attached to anchoring villi (AV) can be seen from which extravillous trophoblasts migrate into the decidual stroma. (B) A cell column of a human placenta at 28 weeks of gestation. The anchoring villus (AV) carries a trophoblastic cell columns with only very few rows of cells (arrow). Below the cell columns multiple interstitial trophoblasts can be found belonging to the type of the large, polygonal cells.

A general feature of all extravillous trophoblasts is the expression of the human leukocyte antigen-G (HLA-G), which differentiates them from the villous trophoblast (McMaster et al., 1995). HLA-G is used as specific marker of extravillous trophoblasts especially in immunohistochemical studies. Another general feature of invading extravillous trophoblasts is the absence of any proliferative activity once these cells have actively started to invade maternal tissues. This is one of the major differences compared to invading tumor cells.

Invasion of extravillous trophoblast is not restricted to early placental development but occurs throughout pregnancy (Fig. 3A and B). The part of the uterine wall below the placenta and invaded by extravillous trophoblasts is termed *placental bed*. The part of the decidua within the placental bed is referred to as *decidua basalis*, while the non-invaded rest of the decidua is termed *decidua parietalis*. The part of the decidua basalis that is delivered with the placenta has been termed *basal plate*. Finally, the part of the decidua that is present in the *fetal membranes*, the *chorion laeve*, is termed *decidua capsularis*.

Trophoblast invasion serves a number of functions that are fulfilled by a respective number of different trophoblast subpopulations (Fig. 4).

Interstitial Trophoblast

Starting within the trophoblastic cell columns, *interstitial trophoblasts* invade into the tissues of the decidua basalis and the inner third of the myometrium within the placental bed (Figs. 3 and 4). Hence, interstitial trophoblast is the source of all other subpopulations of extravillous trophoblast. Besides serving as source for other trophoblast populations, the main function of interstitial trophoblasts is to adhere the placenta to the uterine wall (Benirschke et al., 2006).

On their way through the uterine interstitium interstitial trophoblasts secrete a specific set of extracellular matrix components, called *matrix-type fibrinoid* (Kaufmann et al., 1996), which seems to function as a glue to anchor the placenta to the uterine wall.

The population of interstitial trophoblasts is morphologically and functionally very heterogeneous, and different phenotypes can be distinguished. These phenotypes differ regarding invasive behavior, contact to maternal cells and secretion of matrix components. So far, a molecular basis for these differences has not been established; however, respective attempts to explain differences in trophoblast phenotypes have been made in the mouse (Simmons et al., 2007).

Typically, three different phenotypes can be distinguished within the population of the interstitial trophoblast:

Large, Polygonal Cells

These large, polygonal cells display a large nucleus, are irregularly formed and can be clearly stained for HLA-G and cytokeratin, while they are always negative for proliferation markers such as Ki-67. This phenotype secretes most of the matrix-type fibrinoid and can be found embedded in their own matrix. Hence, contact to maternal cells is rare. The above properties of the cells indicate that the cells are not very invasive, if at all. These cells can be found in the uterus even decades after the last pregnancy.

In early pregnancy (weeks 9–12) about 45% of all interstitial trophoblasts belong to this phenotype. This portion increases throughout gestation with 69% at 16–24 weeks and 89% at 31–39 weeks (Benirschke et al., 2006) (Fig. 3B). This shift in phenotype indicates that trophoblast invasion takes place throughout pregnancy, but is clearly reduced towards term.

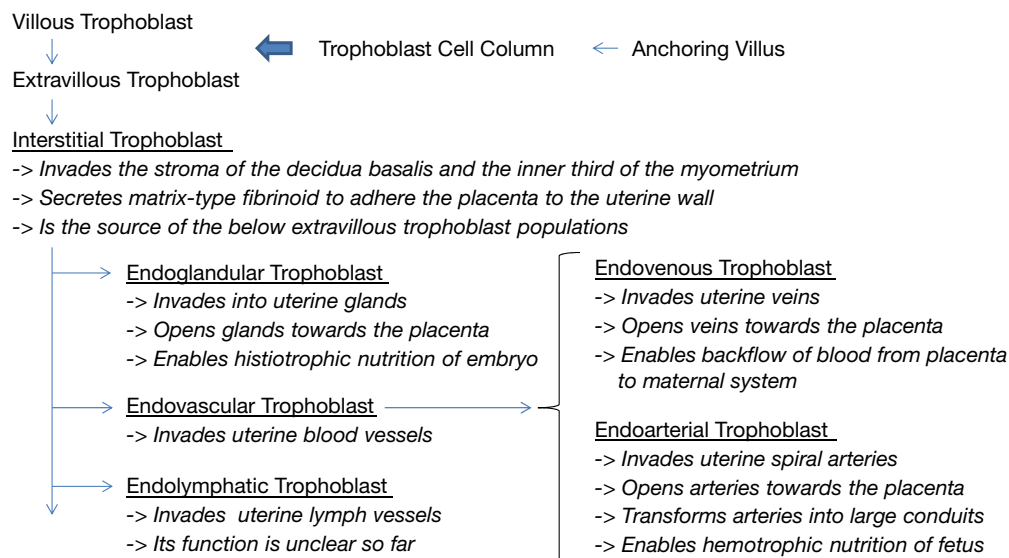

Fig. 4 Subtypes of extravillous trophoblast. Starting with the transformation of villous trophoblasts into extravillous trophoblasts within trophoblastic cell columns, various types of extravillous trophoblast populations can be described.

Small, Spindle-Shaped Cells

These small, spindle-shaped cells large, polygonal cells display small and oval nuclei, are long and slender and can be moderately stained for HLA-G and cytokeratin, while they are always negative for proliferation markers such as Ki-67. This phenotype secretes only small amounts of matrix-type fibrinoid and comes into direct contact to maternal cells. The above properties of the cells indicate that these cells are highly invasive.

In early pregnancy (weeks 9–12) about 55% of all interstitial trophoblasts belong to this phenotype. This portion decreases throughout gestation with 31% at 16–24 weeks and 11% at 31–39 weeks (Benirschke et al., 2006). This shift in phenotype again indicates reduction of trophoblast invasion during pregnancy.

Multinucleated Giant Cells

The difference compared to the above phenotypes is that this phenotype exhibits more than one and up to ten nuclei. These nuclei are irregularly shaped and display varying sizes. These giant cells are much larger than the other interstitial trophoblasts with diameters between 50 and 100 μm (Benirschke et al., 2006). The cells can only hardly be stained for HLA-G and cytokeratin, while they are again negative for proliferation markers such as Ki-67.

Although syncytial fusion of extravillous trophoblasts has never been observed, it is generally accepted that this phenotype is generated by fusion of mononucleated interstitial trophoblasts. This phenotype can mostly be found at the border between decidua and myometrium, while its portion is very low compared to the other phenotypes.

Endoglandular Trophoblast

During the last couple of years the picture of trophoblast invasion has changed dramatically. Until few years ago only invasion into spiral arteries has been the only accepted invasive route of trophoblasts into luminal structures. Today, it has become clear that all luminal structures of the placental bed are invaded by extravillous trophoblasts (Moser et al., 2010, 2015) (Fig. 4).

Already 15 years ago, secretion products of uterine glands have been described in the intervillous space of first trimester placentas (Burton et al., 2002). However, there was no description of any mechanism how these products reach the placenta as uterine glands normally open towards the uterine cavity. Only the description of a directed invasion of uterine glands by extravillous trophoblasts opened the way for a mechanistic correlation (Moser et al., 2010). Today it is clear that *endoglandular trophoblast* erodes and opens uterine glands towards the intervillous space, enabling histiotrophic nutrition of the embryo during the first trimester of pregnancy (Moser et al., 2015; Moser and Huppertz, 2017). Infiltration of uterine glands, displacement of glandular epithelial cells and invasion into the lumen of glands enable opening of the glands and directing them towards the intervillous space of the placenta (Moser and Huppertz, 2017) (Fig. 5).

Endovascular Trophoblast

Endovascular trophoblast is an old term that needs revision. So far it has been used for those extravillous trophoblasts invading into uterine spiral arteries as these vessels have been the only blood vessels where invasion has been described. Today it has become clear

Fig. 5 Invasion of a uterine gland by endoglandular trophoblasts. The images show staining of extravillous trophoblasts for cytochrome 7 (A, C) and for HLA-G (B, C). (C) Shows double staining for both antigens. Staining for cytochrome 7 and HLA-G reveals staining of interstitial trophoblasts in the decidua (blue triangle in A, B) as well as staining of endoglandular trophoblasts invading the gland. Image (A) reveals that staining for cytochrome 7 does not enable to differentiate between staining of glandular epithelial cells and endoglandular trophoblasts, while this is easily possible with staining for HLA-G (B). The red star (A–C) displays the problems arising from single staining for cytochrome 7. The cytochrome 7 stain (A) suggests invasion into a spiral artery with plugging of this vessel by trophoblasts. Respective similar images have been published over the last centuries claiming invasion into spiral arteries. The HLA-G stain (B) reveals that the cells “plugging the vessel” are indeed not at all endovascular trophoblasts but rather detached glandular epithelial cells. The double stain (C) clearly identifies this structure as a uterine gland invaded by endoglandular trophoblasts. Original magnification: $\times 200$. Images courtesy of Dr. Gerit Moser, Medical University of Graz, Austria.

that not only uterine arteries but also uterine veins are invaded by extravillous trophoblasts. Hence, this part of the nomenclature needs revision (Moser and Huppertz, 2017).

Endoarterial Trophoblast

A specific population of extravillous trophoblasts invades towards uterine spiral arteries, percolates the walls of these vessels, displaces the endothelial lining and finally reaches the lumen of the arteries (Kaufmann et al., 2003). This *endoarterial trophoblast* erodes, opens and transforms uterine spiral arteries to enable hemotrophic nutrition during the second and third trimester of pregnancy.

The main function of endoarterial trophoblasts is not only opening of the spiral arteries but most of all their transformation into large conduits that have lost the maternal control on their contractility. It needs to be clarified that widening of these vessels takes place at the very end of the arteries towards the placenta.

Transformation of spiral arteries can be divided into three parts:

1. Maternal factors induce first changes of the uterine spiral arteries very early in pregnancy prior to trophoblasts reaching such vessels. The vessels show reduced organization of vascular smooth muscle cells, altered morphology of endothelial cells and first signs of dilation. It seems as if maternal immune cells trigger these early changes. They accumulate within the decidua in close vicinity to spiral arteries and play an active role in transforming these vessels (Benirschke et al., 2006).
2. After disorganization of the vessel wall and first slight dilation of the vessel, endoarterial trophoblasts percolate from the decidual stroma into the vessel wall. During the very first invasion endoarterial trophoblasts reach the lumen and form plugs to block blood flow towards the placenta (Weiss et al., 2016).
3. Later, endoarterial trophoblasts infiltrate deeper regions of the vessels up to the myometrial portion of the arteries. This results in a further dilation of the vessels, finally reaching a multiple of the original diameter. The reduced activity of smooth muscle cells plus the loss of elastic fibers in the vessel wall further contribute to the dilation effect (Benirschke et al., 2006).

Endovenous Trophoblast

Invasion of extravillous trophoblasts into uterine veins has been described for the first time only very recently by Moser et al., 2017. These authors termed this population of extravillous trophoblast *endovenous trophoblast*. This type of trophoblasts erodes and opens uterine veins within the placental bed to allow backflow of maternal blood from the placenta during pregnancy. This backflow is needed throughout pregnancy and covering histiotrophic nutrition of the embryo as well as hemotrophic nutrition of the fetus (Moser et al., 2017).

The identification of the endovenous trophoblast was already overdue. For decades, invasion of extravillous trophoblast was only accepted to take place into spiral arteries but no other luminal structure in the placental bed. However, if maternal blood flow from uterine arteries into the placenta is established at the beginning of the second trimester, there is the urgent need to have established a respective backflow of blood into the maternal vascular system. Hence, mechanistically, invasion of uterine veins was needed – but never described until 2017 (Moser et al., 2017; Windsperger et al., 2017).

While invasion of spiral arteries comprises invasion, opening and transformation including widening of the vessels, invasion into uterine veins only needs opening and no transformation. Since there is a plasma flow through the endoarterial plugs within the spiral arteries already during the first trimester of pregnancy (Jauniaux et al., 2000), backflow into the maternal system and thus endovenous trophoblast invasion needs to be established very early in pregnancy.

Endolymphatic Trophoblast

Very recently, also invasion into uterine lymph vessels has been described (Windsperger et al., 2017; He et al., 2017). The role of this invasion of *endolymphatic trophoblast* is not clear yet. Maybe, extravillous trophoblasts are much more invasive than thought of so far. They may simply erode and invade any luminal structure that can be found in their invasive pathway.

Placentation in the Mouse

Bryony V Natale and David RC Natale, University of California San Diego, La Jolla, CA, United States

General Introduction

Gestation in the mouse has a range of 19–22 days, with the fertilized one-cell zygote called embryonic day (E) 0.5, the first step of placentation beginning at ~E 4.0 and the functional placenta formed by E 10.5. Though strain dependent, the average litter size in the mouse is 10–12 pups, with an equal number of placentas. The placenta is essential to maintaining a healthy pregnancy and develops as a multipurpose organ. Its purposes include endocrine function that controls maternal adaptations to maintain pregnancy, facilitating nutrient, and oxygen delivery to the embryo/fetus as well as the removal of waste. Trophoblast cells are derived from the embryo and are unique to, and comprise most of the placenta. The mouse placenta, when fully developed has a discoid shape and is hemochorial, meaning that trophoblast cells come in direct contact with maternal blood. At the gross anatomical level, the mouse placenta is comprised of three layers—maternal decidua and two trophoblast-derived layers, the junctional zone (JZ) and labyrinth layer. The mouse, which is commonly used as a laboratory model, has contributed to our understanding of embryonic and placental development. The goal of this article is to review the current understanding of placentation in the mouse including basic development, structure, composition, function, and recent advances in experimental approaches used in the field.

Implantation

The mouse placenta is comprised of many differentiated subtypes of trophoblast cells, which have their own specific function and are restricted to specific placental layers. All trophoblast subtypes are derived from the trophoblast of the blastocyst. After the oocyte is fertilized, the one-cell zygote undergoes several rounds of cleavage divisions, progressing through the 2-, 4-, and 8-cell stages (Fig. 1). During this time, the cells are referred to as blastomeres and are totipotent, meaning that they have the potential to become placenta, yolk sac or embryo proper. It is at the 16-cell, morula stage that the first differentiation event occurs where the totipotent blastomeres diverge to become either trophoblast or inner cell mass (ICM), thereby, facilitating transition to the early blastocyst stage (Fig. 1). The trophoblast gives rise to the trophoblast components of both the placenta and the parietal yolk sac, while the ICM gives rise to the primitive endoderm that becomes the parietal and visceral yolk sacs and the epiblast, that becomes the embryo proper. The Hippo/Lats signaling pathway (Nishioka et al., 2009; Rayon et al., 2016) has been shown to be essential for trophoblast differentiation as it regulates expression of the transcription factors Tead4 and Cdx2, that are required for trophoblast specification. This is followed by a second differentiation event where the cells of the ICM become either epiblast or primitive endoderm (Fig. 1). The trophoblast is the first differentiated cell type of the mouse embryo. It is an epithelial cell type and forms a monolayer of cells that surrounds the embryo at the blastocyst stage. The portion that covers the ICM is called polar trophoblast, and will contribute to the placenta, while the remainder is referred to as the mural trophoblast and contributes to the yolk sac tissues. It is trophoblast that enables embryo implantation and triggers the uterine remodeling that leads to an increase in blood, oxygen, and nutrient supplies. The first step of placentation occurs at ~E 4.0, when the embryo hatches from the zona pellucida (ZP) and the maternal endometrial stromal tissue undergoes decidualization, forming decidua and

Fig. 1 The progression from zygote to blastocyst stage embryo during the first ~4 days of development. Following fertilization, the oocyte and sperm form a one-cell zygote. At the 16-cell morula stage, the first differentiation event occurs leading to specification of blastomeres to become either trophoblast (TE, blue) or inner cell mass (ICM) (purple). The second differentiation event begins at the blastocyst stage where ICM cells become either primitive endoderm (PE, green) or epiblast (EPI, brown). At the late blastocyst stage, just prior to implantation, the trophoblast that covers the ICM is called polar trophoblast, while the remaining TE is mural; the epiblast and primitive endoderm are defined and the blastocyst begins to “hatch” from its zona pellucida (ZP) to begin implantation.

allowing for implantation. The embryo implants (E 4.5) in a process governed by signaling pathways, including WNT signaling, between the trophoblast layer of the embryo and the maternal uterine endometrial epithelium, and through the physical interactions between the two, as the blastocysts attaches to the uterine epithelium. At implantation, the embryo is composed of the trophoblast cells that will contribute to the placenta, the primitive endoderm that will contribute to the yolk sac and the epiblast that will form the embryo proper. At this time, the mural trophoblast at the abembryonic pole stop proliferating and differentiate to form primary trophoblast giant cells (TGCs; Fig. 2A). Primary TGCs are the first terminally differentiated trophoblast subtype, and are highly polyploid due to endoreduplication. This modified cell cycle, in which DNA is continually replicated without any intervening mitosis, is a characteristic of TGCs and can result in DNA content as high as 1024N in these cells, which are also highly invasive and display phagocytic ability. Implantation occurs via the embryo's lateral sides, through uterine epithelial/TGC interaction as they attach to and proceed to invade the decidualizing uterine stroma.

Extraembryonic Ectoderm and Ectoplacental Cone

Following implantation, the polar trophoblast that overlie the ICM, proliferate on the inner side of the blastocyst to form the extraembryonic ectoderm (ExE). This growth then presses down on the epiblast of the ICM which stimulates development of the yolk sac and the proamniotic cavity (Fig. 2A). These proliferating cells are referred to as trophoblast stem (TS) cells and are dependent on fibroblast growth factor 4 (FGF4) (Murohashi et al., 2010; Rappolee et al., 1994) and Nodal (Guzman-Ayala et al., 2004) signaling from the developing embryo epiblast to remain undifferentiated and proliferative. This population is identifiable, histologically, by the expression of TS cell markers (*Cdx2*, *Esrrb*, *Eomes*). As the distance from the epiblast increases, the concentration of FGF4 decreases, causing TS cells to differentiate. These differentiating trophoblast cells form the ectoplacental cone, which as it grows, protrudes into the uterine lumen (Cross et al., 2006) and is considered the first sign of placental development. Both the ExE and ectoplacental cone can be identified in histological sections of the placenta at ~E 5.5–E 6.5. The ectoplacental cone is separated from the epiblast by the ExE and though the inner cells of the ectoplacental cone continue to proliferate and display characteristics of undifferentiated cells, these cells, are no longer TS cells, rather they are self-renewing progenitors that will give rise to the JZ-specific trophoblast lineage later in development. These cells can be identified by *Ascl2*, in histological sections. Simultaneously, the trophoblast cells of the ectoplacental cone that have move outward from the highly proliferative center of the ectoplacental cone and further from the source of FGF4, start to differentiate. These outer cells become bigger and more distant from each other with cytoplasmic projections that allow them to maintain contact with other cells. This process occurs as they become terminally differentiated, nonproliferating, polyploid, invasive secondary TGCs (Fig. 2B). These cells are called the Parietal TGC's and separate the embryonic tissue from the maternal decidua and endothelial cells. They play a role in mesometrial implantation, interaction with the maternal decidua, secretion of regulatory hormones and angiogenesis. TGCs are responsible for opening endometrial capillaries, allowing for blood to percolate in the spaces between the cells, thereby creating blood sinuses.

Chorioallantoic Attachment

Chorioallantoic attachment, marks the beginning of the morphological events that give rise to the fetal blood vessels of the placenta. This process begins, at ~E 7–E 7.5, when one side of the ExE folds within the proamniotic cavity (Fig. 2B) and joins with the ExE on

Fig. 2 The placental development after implantation, between ~E 6.0 and E 7.5. (A) Mural TE differentiate to primary TGCs (dark blue), polar TE forms extraembryonic ectoderm (ExE) which proliferates to expand ExE and also lead to formation of the EPC. The ExE and EPI surround the proamniotic cavity (*). (B) As development proceeds to ~E 7.0, the TGCs surrounding the EPC become larger and more spread out with cytoplasmic projections (dark blue). (C) By E 7–E 7.5, the chorion (Ch) has formed, leading to the division of the proamniotic cavity into the ectoplacental cavity (A), the exocoelom (B), and the amniotic cavity (C). The chorion is composed of a single layer of mesothelium (red) and a single layer of trophoblast, which include trophoblast stem (TS) cells (blue).

the opposite side, thus subdividing the proamniotic cavity and creating the ectoplacental cavity, which is in contact with the ectoplacental cone, and the amniotic cavity, which is in contact with the epiblast, from which the fetus is formed. As the ExE folds, a cavity is formed, thus creating a third space, the chorionic cavity or exocoelom (Fig. 2C). Trophoblast cells line the ectoplacental cavity whereas a layer of extraembryonic mesoderm cells derived from the embryo lines the exocoelom. As a result, the structure that separates the exocoelom from the ectoplacental cavity is composed two layers of cells, a single layer of trophoblast cells, derived from the ExE and a single layer of mesoderm, referred to as chorionic mesothelium. Together, these two layers of cells make up the chorion (Fig. 2C). At ~E 7.5–E 8.0, extraembryonic mesoderm of the exocoelom proliferates to form the allantois, which grows up from the posterior of the epiblast and contacts the basal surface of the chorion (Fig. 3A,B). This process is called chorioallantoic attachment and leads to the formation of the chorionic plate and is a critical event in the formation of the placenta as it precedes and triggers the differentiation of trophoblast cells that are required for the onset of branching morphogenesis. These events mark the beginning of labyrinth formation that leads to the development of the fetal vascular network of the placenta.

Following formation of the chorion and at the time of chorioallantoic attachment, the trophoblast stem cells of the ExE persist, however the closing of the ectoplacental cavity coincides with downregulation of trophoblast stem cell markers in chorionic trophoblast. The closing of the ectoplacental cavity brings the basal surface of the ectoplacental cone in contact with the central surface of the chorion and closes from the center toward the edges. The downregulation of trophoblast stem cell genes matches this pattern, such that by the time this is almost complete, they remain expressed only at the edges of the chorion, only where it is not yet in contact with the ectoplacental cone (Fig. 3B). Following closure of the ectoplacental cavity, the chorion, which was composed of a single layer of trophoblast and a layer of mesoderm cells, starts to expand through proliferation and some contribution from the ectoplacental cone, resulting in multiple layers of trophoblast cells (Fig. 3C).

Branching Morphogenesis and Development of the Labyrinth

The labyrinth layer is responsible for the nutrient, waste, and gas exchange between the mother and fetus and its development begins with the onset of branching morphogenesis that is triggered by chorioallantoic attachment. An important marker of the first step in this process is the expression of the transcription factor, *Gcm1*. Expression of this gene precedes chorioallantoic attachment as it is detectable at ~E 7.5. It is expressed in distinct clusters of 3–4 trophoblast cells that are evenly distributed across the basal layer

Fig. 3 The placental development between ~E 7.5 and E 8.0. (A) Following formation of the chorion, the allantois (mesoderm, red) begins to grow up and toward the basal surface of the chorion. (B) When the allantois contacts the chorion, it spreads across the basal surface. At this point, the ectoplacental cavity begins to close from the centre (arrow) and the chorionic trophoblast (white) contact the trophoblast of the basal surface of the EPC (royal blue, arrow). (C) After closure of the ectoplacental cavity, TS markers are downregulated, the chorion expands through proliferation in preparation for branching morphogenesis.

chorion and its expression is significant because it defines the future sites of branching morphogenesis (Fig. 4A). Following attachment of the allantois, trophoblast cells at these sites differentiate and invaginate toward the ectoplacental cone, thereby forming branch points from which the fetal capillary network will continue to develop (Anson-Cartwright et al., 2000) (Fig. 4A–E).

The mouse labyrinth is triepitheliochorial, meaning there are three distinct layers of differentiated trophoblast cells that separate maternal from fetal blood. Additionally, there is an endothelial cell layer that defines the fetal capillaries. These cells are organized with sinusoidal TGCs in direct contact with and lining the maternal blood spaces (MBS) and immediately adjacent to this layer, are two syncytiotrophoblast (SynT) layers, designated SynT-I and SynT-II, respectively (Fig. 5D(ii) and (iii), respectively). The final layer is endothelial cells that form the fetal capillaries and sit between SynT-II and fetal blood (Fig. 4C–D).

When branching morphogenesis begins, the chorion is composed of proliferating progenitor cells that are positioned to give rise to the organized structure of the mature labyrinth (Fig. 5A). As invagination of the trophoblast proceeds, fetal mesoderm from the

Fig. 4 The stages of the initiation of branching morphogenesis. (A) Prior to chorioallantoic attachment, subsets of cells in the chorion express the transcription factor *Gcm1* (green), which defines future branch points. Expression of *Hand1* identifies progenitors of the S-TGCs (orange) (B) At the time of chorioallantoic attachment, progenitors of the SynT-I cells can also be identified by the expression of specific marker genes (purple). (C) As branching is initiated, *Gcm1*⁺ trophoblast elongate and thin and invaginate toward the developing labyrinth. Mesoderm cells, including differentiating endothelial cells (yellow) move into these developing branches. (D) As the branches develop and endothelial cells interact with trophoblast, the *Gcm1*⁺ cells begin to fuse and differentiate into SynT-II. (E) Branches continue to grow, pushing toward the SynT-I and S-TGC progenitors (purple, orange, respectively). As the *Gcm1*⁺ cells contact the SynT-I cells, the SynT-I cells fuse along their lateral borders. These two cell layers continue to be pushed up, coming in contact with the overlying S-TGC progenitor cells and the branches continue to develop into maternal blood spaces (MBS). Fig. 5 A low magnification image of a histological section of the mature mouse placenta that highlights the gross morphology and below, high magnification images of individual trophoblast subtypes that comprise it. (A) The mouse placenta is composed of three layers; the decidua, the junctional zone (JZ), and the labyrinth. The JZ is highlighted by the expression of the gene *Tpbpa* (blue), which also identified glycogen trophoblast that have migrated into the decidua. (B) SpA-TGCs and maternal uterine natural killer (uNK) cells are found in the decidua surrounding maternal spiral arterioles (i, ii, respectively). (C) Differentiated trophoblast cells found in the JZ include S-TGCs (i), spongiotrophoblast (ii), and glycogen trophoblast (iii). (D) Many different cells contribute to the labyrinth layer including pericytes (i), SynT-I and -II (ii and iii, respectively), endothelial cells (iv), S-TGCs (v), and C-TGCs (vi). All of the trophoblast subtypes and maternal cells that are found in each layer can be identified by the expression of specific genes as shown here by in situ hybridization (B(i); C(i, ii, iii); D(ii, iii, iv, v, iv)) and/or immunohistochemistry (B ii, D i). Magnification: A, 40 ×; B(i), 400 ×; B(ii), 1600 ×; C(i, ii, iii), 1600 ×; D(i), 400 ×; D(ii, iii, iv, iv), 1600 ×; D(vi), 200 ×.

allantois fills in these branch points and development of fetal capillaries follows. *Gcm1*⁺ cells are the progenitors of the SynT-II layer. When fetal endothelial cells (Fig. 5D (iv)) come in direct contact with these predefined branch-points, the *Gcm1*⁺ cells differentiate into the SynT-II cells by thinning and fusing with each other, creating a multinucleated, continuous syncytium (Fig. 4A–D). This occurs after chorioallantoic attachment and the onset of branching. As the branch points elongate the SynT-II cells contact a layer of *SynA*⁺-SynT-I progenitors. The subsequent fusion of these SynT-I progenitors results in formation of the SynT-I layer (Fig. 4B–E). Immediately adjacent to the SynT-I progenitors/SynT-I layer, is the population of trophoblast cells that are

in direct contact with maternal blood sinuses (Fig. 4A–E). These trophoblast cells are proposed to be the progenitors of and differentiate into the S-TGCs (Fig. 5D(v)) and as branching morphogenesis continues, they become the third layer of trophoblast that separates maternal from fetal blood. *Hand1* is required for their differentiation. In addition to the three layers of differentiated trophoblast and the layer of fetal endothelial cells, there is a pericyte population that is derived from fetal mesoderm (Fig. 5D(i)). It is thought that their function is to help direct branching of the fetal capillaries. Interactions between S-TGCs, SynT, endothelial cells, and pericytes are important in fetal branching and for controlling the proliferation of endothelial cells, pericytes, and trophoblast progenitor cells that support the growth and development of the labyrinth. Although the pericyte/trophoblast and pericyte/endothelial relationships are not absolutely defined,

The basic structure of the mature placenta is formed by ~E 10.5 at which time, it is functional in its exchange of nutrients between maternal and fetal blood. During the period of labyrinth development from E 8.5 to E 12.5, growth and increases in cell number are supported by labyrinth-specific trophoblast progenitor cells, which are identified by high levels of expression of the cell adhesion molecule, *Epcam* (Ueno et al., 2013). *Epcam*-expressing trophoblast cells are localized to the chorionic plate and the associated lower regions of the labyrinth. The labyrinth of the placenta continues to grow through cell proliferation and increases in trophoblast number until ~E 12.5. After this time, markers of progenitor populations and proliferation of trophoblast cells are greatly reduced. Between E 12.5 and E 16.5, the volume of the labyrinth increases as the complexity of the vascular network increases. During this period, fetal endothelial cells continue to proliferate however trophoblast cells are thought to increase in size rather than number to support this growth.

Junctional Zone Expansion

The JZ is formed through the proliferation and differentiation of trophoblast cells in the ectoplacental cone. As the labyrinth forms, the cells of the ectoplacental cone proliferate to form a layer of differentiated trophoblast that sit between the labyrinth and the maternal decidua. In addition to blanketing the labyrinth, “fingers” of JZ (both spongiotrophoblast and glycogen trophoblast) are found reaching into the labyrinth (Fig. 5A), which are hypothesized to physically support the labyrinth and through paracrine interactions.

Found within the JZ, are five trophoblast subtypes: spongiotrophoblast, glycogen trophoblast, and the TGC populations, made up of parietal-TGCs, canal-TGCs or spiral artery-associated-TGCs (Fig. 5C(ii, iii, i), D(vi), B(i), respectively). Each of these three subtypes of TGC is distinct in their location within the placenta, the genes that they express and the time at which they differentiate. Based on these characteristics, they are proposed to have distinct functions. As previously noted, parietal-TGCs are the first TGC subtype to differentiate and as the placenta develops, they line the JZ on the decidua side, forming a border that separates the fetal-derived placental from the maternal decidua. The canal-TGCs are found lining the large blood canals that deliver maternal blood from the maternal spiral arterioles in the decidua, through the JZ and down through to the base of the labyrinth (Fig. 5D(vi)), while the spiral artery-associated-TGCs migrate into the decidua and associate with the maternal spiral arterioles (Fig. 5B(i)). The spiral artery-associated-TGCs play an important role in modifying the maternal spiral arterioles that deliver maternal blood to the placenta. Through interactions with maternal uterine natural killer (uNK) cells (Fig. 5B(ii)), remodeling of the extracellular matrix, smooth muscle, and endothelial cell layers occurs. This remodeling, results in low resistance vessels that are lined by spiral artery-associated-TGCs in the decidua, just proximal to their entry into the JZ. Spongiotrophoblast and glycogen trophoblast cells are found within the JZ in clusters and are clearly discernible by E 12.5. Spongiotrophoblast appear dense and compact with slightly larger nuclei than glycogen trophoblast whereas glycogen trophoblast, appear as clusters of “foamy” cells, with clearly identifiable nuclei and seemingly empty cytoplasm, due to the presence of large vacuoles storing glycogen, from which they derive their name. Spongiotrophoblast remain within the JZ and increase in number modestly over gestation, however glycogen trophoblast cells increase significantly in number followed by a migration out of the JZ and into the decidua (migration visible in Fig. 5A) to associate with maternal spiral arterioles. The purpose of this migration is unknown, however, between E 16.5 and E 18.5, the number of glycogen trophoblast are significantly decreased and it is proposed that they release their stored glycogen as energy to support the rapid increase in fetal growth during this time.

Blood Flow and Nutrient Transfer

For the placenta to function efficiently, the maternal and fetal blood must come in close approximation. Maternal blood is delivered to the placenta through the uterine artery to the maternal spiral arterioles; pass through the decidua and into the placenta. As described above, these spiral arterioles undergo remodeling that result in low resistance vessels, which are lined by spiral artery-associated-TGCs (Fig. 6). The spiral arterioles feed into large canals that deliver blood directly to the bottom of the labyrinth. These canals are lined by canal-TGCs. Maternal blood then percolates up through the labyrinth, coming in direct contact with the sinusoidal-TGCs that line the MBS in this layer. This is the site of nutrient and gas exchange. From these spaces, the now deoxygenated blood flows through small channels lined by channel-TGCs and into large lakes called lacunae that empty into uterine veins and returned to maternal circulation. These lakes are lined by parietal TGCs. From entry into the placenta, until exit, the maternal blood is in constant contact with one of five TGC subtypes, in order: spiral artery, canal, sinusoidal, channel, and parietal (Fig. 6). As a result, TGCs are ideally situated to secrete factors directly into maternal blood as it enters the placenta, while it is in the labyrinth and as it exits to return to maternal circulation. Therefore, these factors have the potential to act locally on

Fig. 6 A cartoon image depicting the maternal circulation (*on the left*) and the fetal circulation (*on the right*), over top of a developed mouse placenta. As maternal blood enters the placenta, the system is lined with trophoblast giant cells (TGC). The fetal system is restricted to the labyrinth layer. Maternal blood enters the placenta oxygenated (*red*) and nutrient rich, and leaves deoxygenated (*blue*), while fetal blood enters the placenta deoxygenated and leaves oxygenated and nutrient rich. *Sp-A-TGC*, Spiral Artery-TGC; *C-TGC*, Canal-TGC; *S-TGC*, Sinusoidal-TGC; *Ch-TGC*, Channel-TGC; *P-TGC*, Parietal-TGC.

trophoblast cells within the placenta, as well as in an endocrine manner by influencing maternal physiology through circulation in the maternal blood.

The deoxygenated fetal blood enters the placenta through the umbilical artery at the chorionic plate, where the vessel branches and blood is delivered to endothelial lined fetal capillaries within the labyrinth. Within the labyrinth layer, the structure and organization of fetal capillaries provides a massive surface area to facilitate nutrient and gas exchange. This is further enhanced by the close opposition of the maternal and fetal blood spaces, and the relative short distance across the four cell layers, which is referred to as the interhemal membrane. As gestation proceeds and the fetal capillary network of the labyrinth continues to develop, it becomes more complex and the interhemal membrane becomes thinner, measuring as small as 4–10 μm in places toward the end of gestation. This promotes nutrient transfer in two ways: (1) it provides an increased surface area and (2) a thinner interhemal membrane means a reduction in the distance separating maternal and fetal blood. Oxygen and CO_2 diffuse across the interhemal membrane freely and the uptake and transfer between maternal and fetal blood of amino acids, glucose and other molecules required for fetal growth and development, is facilitated by numerous transport proteins in the trophoblast cells. Fetal blood leaves the placenta (at the chorionic plate), through the umbilical vein in the umbilical cord to return oxygenated, nutrient rich blood to the fetus (**Fig. 6**).

The trophoblast cells of the labyrinth layer also act as a barrier to pathogens, drugs, and other molecules from the dam that may be detrimental to fetal health. Labyrinth trophoblast cells metabolize maternal glucocorticoids from their active to inactive form through the expression of 11 β HSD2 in the SynT. This activity is important to limit fetal exposure to glucocorticoids during gestation, which can cause growth restriction at early stages. Toward the end of pregnancy, glucocorticoid metabolism is altered, as increased levels are required for fetal lung development, prior to parturition.

Endocrine Function

In addition to nutrient/gas exchange, metabolism, and transport, the placenta plays a critical role as an endocrine organ during pregnancy. In this capacity, trophoblast cells produce a vast array of secreted factors that include: peptide and steroid hormones, growth factors, and cytokines (Evain-Brion, 1999; Soares et al., 1996; Solomon, 1988). Among their many functions, these factors act to: support and maintain pregnancy, modulate maternal physiology to adapt to pregnancy, control the onset of parturition and support embryonic/fetal development and growth. Mouse trophoblast do not make the human chorionic gonadotropin (hCG) that is seen in primate trophoblast. Instead the mouse TGCs, glycogen trophoblast, and spongiotrophoblast all express placental lactogens and prolactin-related proteins in cell-specific patterns throughout gestation. These proteins signal through the prolactin receptor and early in gestation, expression by TGCs acts to maintain progesterone production by the corpus luteum in the ovary which is essential for maintenance of pregnancy. Genes in this family have also been shown to regulate angiogenesis and likely have many as-of-yet unidentified roles throughout gestation.

Placentation as a Model for Human Diseases

The gross anatomy of the mouse and human placenta is quite different though functionally, they are very similar. Many of the genes and pathways that are important in mouse placental development and function, are conserved in the human. For this reason, studying placentation in the mouse has been very useful in understanding how human placental development is controlled, making it a popular model. Advantages of using the mouse include the knowledge of mouse genetics and the antibodies and experimental resources available as a result. The physiology of mice is well understood and they are relatively easy and inexpensive to obtain and

house, especially when compared to large animal or primate models. Mice have a short gestation, reach sexual maturity quickly and reproduce easily.

There are differences that do exist that should be considered, including the fact that in studying mouse pregnancy, there are multiple fetoplacental units which are linked by maternal blood flow and can therefore interact and influence each other. Additionally, maternal physiology is slightly different in litter-bearing species with respect to maternal adaptation to pregnancy. Finally, in the mouse, fetal development at the time of birth is immature with respect to human and therefore, placental function later in gestation may be slightly different. Despite these differences, the mouse is still a powerful model and perhaps most significantly, because the mouse genome can be targeted and using transgenic approaches, manipulated to misexpress, overexpress or eliminate completely, the expression of almost any gene.

Investigators have used transgenic approaches to manipulate the expression of targeted genes (i.e., knock out or knock in) to gain insight into their role in placental development or placental function later in gestation. At the time of writing, over 200 transgenic mouse models have been described with a phenotype related to placental development or function and thereby, detrimental to fetal health and growth. Advances in transgenic technologies have allowed experiments to be conducted in a cell-specific manner. These technologies include the Cre/LoxP approach, which enables experiments to be conducted in a cell-specific manner and/or with the ability to manipulate the timing of gene expression. The use of lentiviral vectors allows for the specific targeting of the trophoblast cells in the placenta, by exposing only the outer trophoctoderm layer of the embryo to nonreplicating lentiviral particles that contain either expression constructs or shRNAs to overexpress or knockdown expression of a specific gene.

Placental insufficiency can lead to fetal growth restriction or fetal demise and has been widely studied in the mouse. Both transgenic mouse and surgical models have been used to understand placental insufficiency and compromised placental environments. In the RUPP (reduced uteroplacental perfusion pressure) model, the uterine arteries are surgically ligated late in gestation to reduce blood flow to the fetoplacental units. This model, results reliably in fetal growth restriction and mimics symptoms of preeclampsia, including maternal hypertension, and proteinuria (Fushima et al., 2016). Other described models include: exposing pregnant mice to alcohol, cigarette smoke, hypoxia, environmental toxicants, altered diet (low calorie, high calorie, low protein, high fat), maternal diabetes, and have been shown to influence placental function and/or development as well as fetal growth. Identifying both the similarities and the differences in the altered placental function or fetal growth allows for a better understanding of placental development and function as it relates to placental pathologies. Through the use and study of mouse models, scientists gain an understanding of human placental pathologies that cannot be investigated in the same depth and detail through the study of human tissue. In conclusion, understanding mouse placentation is not only important for the purpose of placenta biology, but rather should be additionally considered in all mouse models that include genetic manipulation, as poor placental health or compromised placental circulation may affect the developing fetus. In addition to the immediate health impact on the fetus, the placenta environment is considered a factor in fetal programming of adult health, and thus a placental assessment should be included in all phenotypic assessment of mouse transgenic models.

Introduction

Pregnancies in the livestock species, here represented by pigs, sheep and cows, share the key events of early embryo development, conceptus (embryo/fetus and associated placental membranes) elongation, pregnancy recognition, implantation, and establishment of functional placentation.

The early stages of embryo development in pigs, sheep and cows proceed in a manner similar to other mammalian species (Fig. 1). After fertilization within the oviduct, the zygote undergoes the first cleavage division to form the 2-cell embryo, and cleavage divisions continue through the 8–16 cell stage, when transcriptome activation occurs. These divisions culminate in formation of the solid mass of cells, called the morula, that remains encased in the zona pellucida of the original egg. Embryos remain in the oviduct before entering the uterus at 60–72 h in pigs, 72 h in ewes, and 72–96 h in cows. Embryos of most species fail to develop beyond the early blastocyst stage if confined to the oviduct, due perhaps to the absence of critical factors required for embryonic development that are supplied by the uterus. The developing embryo next forms the blastocyst. At this point the pluripotent blastomeres begin to differentiate into the inner cell mass (ICM) and trophoblast to begin the cell lineages that will eventually become the embryo/fetus proper (primitive ectoderm, mesoderm and endoderm), and the placental chorion, respectively, and are collectively termed the conceptus (Bazer et al., 2005).

The blastocyst hatches out of the zona pellucida and increases in size before undergoing a rapid morphological transition called elongation (Fig. 1). The small spherical conceptus grows into a long tubular form with the trophoblast and endoderm cells migrating towards the ICM to form the elongation zone. The tubular conceptus then begins to increase in length and decrease in diameter due to the migration of trophoblast and endoderm cells towards the ends of the conceptus to produce the filamentous form. Conceptuses elongate from spherical to filamentous forms primarily due to trophoblast remodeling. The next phase of growth is very rapid and is dependent primarily on cell proliferation to form the mature filamentous conceptus. During the early elongation period, the conceptus remains free-floating and dependent on the uterus for nutrients. Conceptus elongation provides increased surface area for nutrient exchange between the conceptus and uterus and helps inhibit luteolysis for pregnancy recognition (Bazer and Johnson, 2014).

The peri-implantation conceptuses of pigs, sheep, and cows secrete pregnancy recognition signals that act in a paracrine manner on the uterus to exert antiluteolytic effects that prevent uterine release of luteolytic prostaglandin $F_{2\alpha}$ (PGF) to maintain the corpus luteum for production of progesterone, the hormone of pregnancy (Fig. 2). This event is critical for a successful pregnancy. During the period of pregnancy recognition, progesterone down-regulates expression of progesterone receptors in the uterine luminal (LE) and glandular epithelium (GE). The loss of progesterone receptor expression by these epithelia appears to be prerequisite for progesterone to stimulate production and secretion of histotroph, a mixture of hormones, growth factors, nutrients, and other substances required for growth and development of the conceptus and implantation (Bazer et al., 2012).

The process of implantation is highly synchronized, requiring reciprocal secretory and physical interactions between a developmentally competent conceptus and the uterus during a restricted period of the uterine cycle termed the “window of receptivity.” The initial interactions between apical surfaces of uterine LE and trophoblast begin with sequential phases i.e., nonadhesive or precontact, apposition, and adhesion, and conclude with formation of a placenta that supports fetal-placental development throughout pregnancy (Fig. 3). Conceptus attachment first requires loss of antiadhesive molecules in the glycocalyx of uterine LE, comprised largely of mucins that sterically inhibit attachment. This results in “unmasking” of molecules, including selectins and galectins, which contribute to initial attachment of trophoblast to uterine LE. These low affinity contacts are then replaced by a repertoire of adhesive interactions between integrins and maternal extracellular matrix (ECM) molecules that appear to be the dominant contributors to stable adhesion at implantation. Implantation can be defined as the beginning of placentation (Johnson et al., 2014).

Considerable variability exists relative to histogenesis and organization of the placenta; however, trophoblast interactions with maternal uterus remain extensive in all species studied, and this allows for the close juxtaposition of the microcirculatory systems of the uterus and placenta for the transport of nutrients from the mother to the embryo/fetus. Pigs have a true epitheliochorial placenta in which there is no displacement or invasion of the maternal uterine tissues. Ruminants have synepitheliochorial placentae in which binucleate trophoblast cells migrate, invade, and fuse with uterine LE to form multinucleated syncytia in aglandular areas of the uterus where placentomes form. In both epitheliochorial and synepitheliochorial placentation, the conceptus remains within the uterine lumen throughout gestation (Bazer et al., 2012).

Early Pregnancy, Implantation, and Placentation in Pigs

The pig embryo moves from the oviduct into the uterus 60–72 h after onset of estrus, and reaches the blastocyst stage by day 5. The spherical 0.5–1 mm diameter blastocyst sheds the zona pellucida between days 6 and 7 and expands to a 2–6 mm diameter by day 10. At this stage development of pig embryos diverges dramatically from rodents or primates, and the presumptive placental

Fig. 1 Early embryonic development generalized for pigs, sheep and cows. Adapted from Bazer, F. W., Johnson, G. A., and Spencer, T. E. (2005). Growth and development: Pre-implantation embryo. In: *Encyclopedia of animal science*, (eds.) Pond, W. G. and Bell, A. W. NY.: Marcel Dekker, Inc., Vol. 1, No. 11–13, pp. 1–3.

membranes (trophoblast and endoderm) elongate rapidly to a filamentous form by day 16. Blastocysts expand at about 0.25 mm/h from the early spherical blastocyst stage to the 4–9 mm diameter spherical blastocyst stage. Then a remarkable increase in the rate of elongation to 30–45 mm/h from the 10 mm blastocyst to the 150–200 mm long filamentous conceptus occurs within a few hours. A dense band of cells (the elongation zone) composed of both endoderm and trophoblast extends from the ICM to the tip of the ovoid blastocyst on day 10. After formation of the elongation zone, there is further rapid elongation of the 100–200 mm long conceptus to a conceptus of 800–1000 mm in length by day 16 of pregnancy mediated through alterations in microfilaments and junctional complexes of trophoblast cells and formation of filopodia by endodermal cells. This last period of elongation involves cellular hyperplasia and each conceptus within the litter achieves maximum surface area for contact between trophoblast and uterine LE to facilitate uptake of nutrients from uterine LE and uterine GE, which increase coincidentally with elongation of the conceptuses (Bazer and Johnson, 2014).

Available evidence indicates estradiol is the pregnancy recognition signal in pigs. Estradiol, produced by day 10–12 pig conceptuses, redirects uterine LE secretion of PGF. In the absence of estradiol, PGF is secreted into the uterine venous drainage (endocrine secretion), where it has access to the corpus luteum and causes luteolysis. In the presence of estradiol, PGF is secreted into the uterine lumen, where it may be converted to prostaglandin E2 or to its inactive metabolite, 13,14-dihydro-15-keto-PGF, by the uterine endometrium and/or conceptus. The result is maintenance of progesterone production by the corpus luteum, and progesterone then down-regulates progesterone receptor in the uterine LE by day 10 and in the uterine GE by day 12 of pregnancy. A major role for both estradiol and progesterone is to stimulate the production and secretion of histotroph that supports conceptus

W. pp. 137–164.

development and implantation. Histotroph secretion is coincident with down-regulation of progesterone receptors in LE, and estradiol and progesterone induce expression and secretion of histotroph from the uterine LE and GE, respectively (Bazer and Johnson, 2014).

The term “implantation” is somewhat a misnomer for the pig, but nevertheless, it is used to describe the initial stages of placentation in the livestock species. Pigs demonstrate true epitheliochorial placentation in which there is no displacement or invasion of the maternal tissues and the conceptus remains within the uterine lumen throughout gestation. Throughout implantation, days 13–26 of pregnancy in pigs, the glycocalyx that extends from the apical surface of the uterine LE is thicker than the glycocalyx at the surface of trophoblast. On days 13 and 14 the uterine LE develops protrusions that become enclosed by caps of trophoblast cells that serve to physically immobilize the conceptus, and by day 14 there is close apposition between the apical plasma membranes of trophoblast and uterine LE cells. Interdigitating microvilli form between these plasma membranes on days 15 and 16, and then the interface becomes increasingly complex over days 15–20. This transition is characterized by the development of apical domes on the LE that are closely related to the trophoblast, and provide long cytoplasmic extensions into a luminal space between the apical domes. Finally, adhesion transitions into placentation through ever-increasing development of interdigitating microvilli between the uterine LE and trophoblast by day 26 of gestation (Dantzer 1985).

In epitheliochorial placentation, separation of fetal and maternal blood is always maintained by an elaborate array of endometrial and extraembryonic fetal tissues that represent a potential barrier to hemotrophic (nutrients carried in the blood) nutrient transport from the mother to fetus. Thus, the interhaemal distance in pigs must be minimized. This is initially accomplished through degradation of much of the connective tissue separating the uterine LE and trophoblast/chorion (referred to as trophoblast throughout this paragraph) from their underlying capillary beds resulting in the blood vessels actually indenting into the basal surfaces of uterine LE and trophoblast cells. Surface area of contact between the uterus and placenta is increased through interdigitation of microvilli between uterine LE and trophoblast. However, between day 25 and day 30, extensive remodeling of the uterine-placental interface to form chorionic (placental) ridges and corresponding endometrial invaginations results in folding that further increases the area of uterine-placental association across the entire placenta, except at the openings of uterine glands (Fig. 4). In addition to having uterine LE closely apposed to the trophoblast, there are specialized chorionic epithelial cells at the openings of the mouths of uterine glands where the trophoblast never fuses with the uterine LE, but forms a pocket referred to as an areola. Histotroph from the uterine GE is delivered into these areolae and is absorbed and transported across the chorion by fluid

Fig. 4 The uterine-placental interface of mature placentation in the pig illustrating folding for hemotrophic and an areola for histotrophic support of the fetus.

phase pinocytosis for release into the placental circulation. The placenta of each piglet in a litter has about 2500 areolae and their number correlates with fetal weight. The trophoctoderm cells that line the areolae and line the tops of the placental ridges of the folds are tall columnar epithelia, well suited for transport of nutrients across the epithelial barrier (Song et al., 2010).

Early Pregnancy, Implantation, and Placentation in Sheep and Cows

Sheep and cows share many features of early embryonic development and implantation with pigs. The morula enters the uterus on day 4 postfertilization in sheep (days 4–6 in cows), and the blastocyst is formed by day 6. Before sheep and cow blastocysts develop into a conceptus, they “hatch” from the zona pellucida on days 6–7 or 9–10, respectively. Sheep blastocysts are spherical on day 4 (0.14 mm) and day 10 (0.4 mm), elongate to the filamentous form between days 12 (33 mm) and 15 (150–190 mm), and extend through the uterine body into the contralateral uterine horn by days 16–17 of pregnancy. Cow blastocysts are spherical on days 12–14 (2 mm on day 13), elongate to 60 mm by day 16, and reach 200 mm by day 19. In sheep, the filamentous conceptus is closely associated with the uterine LE and appears to be immobilized within the uterine lumen by day 14, although the conceptus can still be recovered intact from the uterus by lavage with only superficial damage. Apposition begins near the inner cell mass, and spreads towards the ends of the elongated conceptus, and by day 16 (sheep) and day 19 (cows), the trophoctoderm is firmly attached to the uterine LE with significant interdigitation between the microvilli on uterine LE and trophoctoderm cells. As sheep and cow conceptuses elongate and attach to the uterine wall, they synthesize and secrete interferon (IFN) τ , the signal for maternal recognition of pregnancy, from day 10 to day 21 in sheep, peaking on day 14 in sheep and day 20 in cows. IFN τ acts on the uterine LE and superficial GE to inhibit transcription of the estrogen receptor α gene. This precludes estrogen receptor α from stimulating an increase in oxytocin receptors in uterine LE, thereby preventing oxytocin from inducing release of luteolytic pulses of PGF. The result is maintenance of the corpus luteum, the source of progesterone required for the production of histotroph for a successful pregnancy (Spencer and Hansen, 2015).

In contrast to the pig, sheep and cows demonstrate synepitheliochorial placentation in which limited fusion of trophoctoderm with uterine LE occurs. Two morphologically and functionally distinct cell types, mononucleate trophoctoderm cells and binucleate trophoblast giant cells (BNCs), are present in the trophoctoderm of ruminant placentae (Fig. 5). The mononucleate cells constitute

Fig. 5 (A) Syncytialization at the uterine-placental interface of sheep. (B) Syncytialization at the uterine-placental interface of cows.

Fig. 6 (A) Structure of a placentome for hemotrophic support of fetal development. (B) Structure of an areola for histotrophic support of fetal development.

the majority of the trophoblast cells and BNCs begin to differentiate from the mononucleate trophoblast cells in concert with trophoblast outgrowth during conceptus elongation. BNCs first appear between days 14 and 16, and days 17 and 19 of gestation in sheep and cow conceptuses, respectively, and comprise 15%–20% of the trophoblast during the apposition and attachment phases of implantation. BNCs migrate and fuse with individual uterine LE cells to form trinucleate syncytial cells (beginning about day 16 of pregnancy in sheep, day 20 of pregnancy in cows), thereby assimilating the LE. The syncytia of sheep subsequently enlarge through continued BNC migration and fusion to form syncytial plaques (Fig. 5A). The syncytial plaques are conceptus-maternal hybrid cells that are composed of uterine LE and BNCs, and they eventually form the epithelial interface between uterine and placental tissues within the placentome (described in the next paragraph). In sheep, the syncytial plaques are a consistent feature in the placentomes throughout pregnancy. In cattle, BNC-uterine LE fusion to form syncytia is limited to the production of only transient trinucleate syncytial cells throughout pregnancy (Fig. 5B) (Wooding, 1984).

Following successful elongation of the conceptus, trophoblast outgrowth, and implantation, the placentae of sheep and cows, organize into placental and interplacental regions (Fig. 6). During placental development, highly branched villous placental folds, termed cotyledons, initially form by day 30 of gestation in sheep. Cotyledonary chorioallantoic villi lined by syncytial plaques then begin to protrude into crypts in the maternal endometrial caruncular tissue (aglandular areas of endometrium consisting of stroma covered by a single layer of uterine LE), resulting in extensive interdigitation of endometrial and placental tissues by day 40. Placentomes provide a conduit for hemotrophic nutrition to the fetus where maternal and placental blood vessels are in close proximity for exchanging oxygen and micronutrients, and there is a close correlation between placental mass and birth weight of the fetus. In contrast, interplacental areas exhibit epitheliochorial attachment of uterine LE to trophoblast, and contain areolae that take up histotroph secreted by the uterine GE for transport to placental vasculature that rings the areola (Wooding and Burton, 2008).

Placentation: Consolidating the Fetal–Maternal Relationship

Placentation is the establishment of a physical connection between the maternal and the fetal organisms inside the body of the mother (Ramsey, 1982; Mossman, 1987; Wooding and Burton, 2008). The placenta is thus a composite organ consisting of fetal and maternal tissues, although the terminology varies between authors. Some authors prefer to only call the fetal component “placenta” while others include the fetal-maternal interface together with the fetal placental structures. Given the high degree of integration between the fetal and maternal organisms during placental development it seems biologically more meaningful to include both the fetal and the maternal components in a discussion of placentation. This is particularly appropriate when fetal and maternal cells are highly intermixed, as it is the case in humans and apes.

The manifest purpose of placentation is maternal provisioning of nutrients and oxygen to the fetus and also waste removal from the embryo or the fetus (Wooding and Burton, 2008). Placentation is thus the major alternative to provisioning the developing embryo through yolk. The evolution of placentation is thus correlated with a decrease in the amount of yolk provided to the oocyte (egg cell), and in mammals even the loss of genes for egg yolk genes (Brawand et al., 2008). Somewhat intermediate ways of maternal provisioning between yolk and placentation also exist. For example in some sharks (mackerel sharks, Lamniformes) the fetus develops inside the mother and is nourished by yolk rich eggs that the mother continues to ovulate and which are eaten by the fetus during intra-uterine growth (Hamlett, 1989). Even fratricide has been reported where one of the growing shark fetuses eats his/her brothers and sisters as a source of nutrition, as found in Sandtiger sharks (*Carcharias taurus*). Less dramatic forms of nonplacental maternal provisioning consist of uterine secretions that are either taken up through the eggshell or eaten by the fetus as in the false cat sharks (Pseudotriakidae) and viviparous salamanders (e.g., *Salamandra maculatus*).

Placentation evolved many times, both within the vertebrates as well as invertebrates. For instance some of the so-called velvet worms (Onychophora, Para-arthropoda, i.e., relatives of arthropods) have a placenta (Anderson and Manton, 1972). Within vertebrates, placentation is found in all major groups, with the exception of jawless vertebrates, lampreys and hagfish. The latter’s lack of placentas may simply reflect the small number of species alive today rather than a biological constraint against evolving placentation. The fetal and the parental structures involved in placentation vary. Briefly, in sharks the placentas develop from apposition of the yolk sack to the oviduct of the mother (Hamlett, 1989); in teleosts placentation can occur either within the ovary itself (Wourms, 1981), or within a skin pouch of the father (seahorses and pipefish, Syngnathidae) (Stolting and Wilson, 2007). In reptiles, placentation is particularly frequent in squamates (lizards and snakes) (Blackburn and Flemming, 2009; Pyron and Burbrink, 2015) but absent among extant archosaurs (crocodilians and birds). Variation of mammalian placentation will be discussed in greater detail below.

The Fetal–Maternal Relationship in Mammals

In mammals, the only maternal space of placentation is the uterus. This is not self-evident when one compares mammalian placentation with the variety places that accommodate placentation in teleost fishes (see above). The uterus is homologous to the shell gland of egg laying (oviparous) reptiles and monotremes (Lombardi, 1998). It shares its principle structure with the shell gland consisting of a smooth muscle myometrium, lined internally by the so-called endometrium. The endometrium consists of an epithelium that continues into endometrial glands and an endometrial stoma. The stroma is made up of endometrial fibroblasts, macrophages and natural killer cells, as well as blood vessels and capillaries. Of these endometrial cells the luminal epithelium, the endothelium of the blood vessels, the maternal blood and the endometrial stromal fibroblasts are the main maternal contributions to the fetal-maternal interface. The epithelium can be a permanent structure of the F-M interface or can be eroded during the process of implantation. In the latter case the F-M interface is principally formed by endometrial fibroblasts which then differentiate into a quasi-epithelial cell type, called decidual stromal cell.

The term decidua originally signified the parts of the uterine lining that is extruded together with the placenta, after the neonate has been born, i.e., the tissue of the mother that gets “lost” during childbirth (decidua = gr. “falling off”). Over the centuries, the term has changed in meaning, and now often refers to the differentiated form of endometrial fibroblasts, which are a specialized cell type that evolved to accommodate and contain the invading fetal portion of the placenta. Consequently decidual cells are not found in mammals that have a noninvasive placenta, e.g., cows, sheep, horses etc.

The fetal contribution to the placenta, or the “placenta proper” according to some authors, develops from extra embryonic tissues of the embryo in mammals and reptiles. There are four principal kinds of extra-embryonic membranes we need to distinguish in an amniote embryo: the chorion, the amnion, the yolk sac and the allantois (Fig. 1). The topological relationships among these membranes is variable and cannot be adequately reviewed here. The interested reader is encouraged to consult the short but very clear and accurate summary by Elizabeth Ramsey (Ramsey, 1982).

In brief, the chorion is the tissue layer that surrounds the embryo and all the deeper lying extraembryonic membranes (Fig. 1). The cells of the chorion are also sometimes called trophoblast cells since in eutherian development the outermost layer of cells in

Fig. 1 The topological relationships among the principal extraembryonic tissues of an amniote vertebrate embryo.

the early embryo is called the trophoblast. The amnion is a bubble surrounding the embryo, and the yolk sac and the allantois are growing out of the belly of the embryo from the embryonic gut, the endoderm. In all vertebrates with yolk rich eggs the yolk sac, naturally, covers the yolk of the egg and is the principle conduit through which the embryo can access the nutrients stored in the egg yolk. In spite of its yolk related origin, a structure homologous to the yolk sac of reptiles, birds and fishes, is also found in eutherian mammals in spite of the fact that there is no yolk in a eutherian egg cell (Ramsey, 1982). Eutherian mammals have no yolk in their egg cells, because they evolved a complete reliance on nutrient transfer from the mother through the placenta. Never the less a structure homologous to the yolk sac develops which transiently can contribute to the placenta, and has a role in blood development. Finally, the allantois originated as a container for the fetal urine and also serves as a structure of gas exchange through the egg shell. Is also grows out of the belly of the embryo and is also found in the same space as the yolk sac (Fig. 1). The intra-embryonic portion of the allantois later develops into the urinary bladder.

The fetal placental structures in mammals, as well as in reptiles, derive from either the yolk sac or the allantois or both. The contribution of either to the placenta changes during evolution, with a dominant contribution from the yolk sac in earlier branching lineages of mammals (Tyndale-Biscoe and Renfree, 1987; Freyer et al., 2003), and a stronger contribution of the allantois in more derived (later evolved) forms. This shift from yolk sac to allantois derived placental structures does not only occur during evolution, but can also happen during development, where earlier in fetal life the yolk sac may dominate and gradually being replaced by structured derived from the allantois.

In mammals, the placenta is the most variable organ between species. For that reason, a number of complementary classification systems have been developed, the main ones are based on the degree of intimacy between the fetal and the maternal tissues, the fetal structure forming the placenta, and the morphology of the fetal part of the placenta itself.

A broadly used classification is based on the number of tissue layers that separate the fetal and the maternal blood compartment (Grosser, 1927). The principal differences among placental types arise from the number of maternal tissue layers removed during implantation. The least invasive placentation is called the epithelio-chorial placenta. Its name derives from the name of the maternal and the fetal tissue that come into contact: the luminal epithelium of the uterus (maternal) and the chorion of the fetus (Fig. 2A). This form of placentation is found in many marsupials and in a large group of eutherian mammals, represented by the hoofed animals, like pig, cow, horses and their relatives, including whales and dolphins. Some smaller groups of eutherians also have

Fig. 2 The three main forms of the fetal-maternal interface classified according to Grosser (1927). (A) Epitheliochorial placenta, the chorion of the fetus attaches to the luminal epithelium of the uterus. (B) Endotheliochorial placenta, the embryo erodes the luminal epithelium and the chorion is in contact with the maternal blood vessels. (C) Hemochorial placenta, the maternal epithelium and blood vessels are eroded and the fetal chorion is bathed in maternal blood.

epithelia-chorial placenta, such as the Strepsirhini (lemurs, galagos and lorises) and dugongs. These groups, marsupials, hoofed animals, Strepsirhini and dugongs are distantly related to each other and thus their epithelio-chorial placenta is independently evolved.

A more invasive form of placentation is called the endothelio-chorial placenta, where during implantation the uterine epithelium is eroded as is part of the stroma and the chorion of the fetus is only separated from the maternal blood by the lining of the blood vessels, the endothelium (Fig. 2B). This form of placentation is found in carnivores, cats and dogs and their relatives, as well as elephants, the armadillo and many bats.

The most invasive placenta is the hemochorial placenta, where the fetal cells of the chorion are directly in contact with the maternal blood after the uterine epithelium and the blood vessels have been partially destroyed by the invading conceptus (Fig. 2C). This form of placentation is wide spread among eutherian mammals, including the rodents and humans.

This formal classification of the FM interface hides a large amount of biological differences that exist within each category. Epithelia-chorial placentae can either consist of an attachment of the chorion to the maternal epithelium, but more intimate forms also exist. For instance, in the opossum the cells of the chorion interdigitate between the maternal epithelial cells, rather than just attach to the surface of the epithelium (Freyer et al., 2002). Furthermore, it is possible that the chorial and the maternal cells fuse, forming cells that contain both maternal and fetal cell nuclei. This has been documented in sheep and the distantly related bandicoots (Padykula and Taylor, 1976), a marsupial. Even among the hemochorial placentae, the nature of the fetal invasion can vary greatly between species (see below). For instance the human and ape placenta includes not only a partial destruction of the endometrium, including the blood vessels, but also a replacement of the maternal endothelium (the inner lining of the blood vessels) of the spiral arteries as well as migratory cells, so-called extravillous trophoblast cells, that invade as far as the myometrium.

The second aspect of the placenta that can be used to classify a mammalian placenta is the fetal tissue contributing to the definite placental structure. As mentioned above, there are three principal fetal tissues that contribute to the placenta: the chorion, the yolk sack and the allantois. In most forms of placentation the outermost layer is formed by the chorion, often also called the trophoblast. The inner tissue layers of the placenta can either be formed by the yolk sack or the allantois, and thus we can distinguish between chorio-vitelline placenta made up from the chorion and the yolk sack, and a chorio-allantoic placenta. The chorio-vitelline placenta is dominant in marsupials and some eutherians, like the rabbit (Freyer and Renfree, 2009). In contrast, most eutherians have a chorioallantoic placenta (Ramsey, 1982). An exception to the rule that the outermost layer of the fetal placenta is composed of chorion cells is the so-called “inverted” yolk sack placenta. In this case the chorion and part of the yolk sack is eroded so that the fetus contacts the mother with the inner surface of the yolk-sack, which leads to a situation where the yolk-sack tissue seems to lie “outside” the chorion. This special form of placentation is found in rabbits and most rodents (Ramsey, 1982).

A peculiarity of the mammalian fetal-maternal interface is that cells in this part of the body have a tendency to fuse and form of either syncytial structures, i.e., structures where multiple nuclei are found in the same continuous cytoplasmatic body. The most frequent form, also found in humans, is where the fetal surface of the placenta is made of fused trophoblast cells, the so-called syncytio-trophoblast. Cell fusion can also occur between maternal and fetal cells, leading to cells containing both, fetal and maternal nuclei, so-called heterokaryons. The latter has been described in some marsupials (bandicoots) and in sheep. This tendency to cell fusion is driven by the expression of retroviral envelop proteins called syncytins (Huppertz et al., 2006), which probably are expressed at the placenta because they also ameliorate the maternal immune response (Mi et al., 2000).

Finally, the oldest classification of placentas is based on the overall morphology of the term placenta, i.e., the morphology of the placenta at the end of pregnancy (Fig. 3). The morphological classification is based on the external shape of the chorioallantoic part of the placenta. In the mature placenta the surface area is increased by folds or projections (villi) according to the same principle as other metabolic exchange surfaces increase in surface area (villi in the gut for instance). The morphological classification is then based on the distribution of these folds and projections. If these structures are distributed all over the surface one talks about a diffuse placenta. This form is for instance found in the pig and the horse. In the cotyledonary placenta the folds or villi are concentrated into a small number of groups, called cotyledones or placentomes. This form is found in ruminants, like the cow. If the projections are located in a belt around the fetus the placenta is called “zonary” and is characteristically found in carnivores, e.g., cats and dogs with exceptions, like the bear. Finally, if the exchange surface is concentrated in one larger disc the placenta is called discoidal. This form is found in humans and other anthropoid primates (new world monkeys, old world monkeys and apes), rodents (mice and rats) as well as bears.

The Evolving Fetal–Maternal Relationship in Mammals

A simple listing of the various forms of placentation as summarized above is highly confusing, since it does not distinguish between ancestral and evolved forms of placentation, which formally would fall into the same class of placentas but hide the often fundamentally different biology behind them. For that reason, it is important to briefly summarize the evolution of the fetal–maternal relationship in order to put these descriptive categories into context.

Living mammals consist of three major groups, monotremes, marsupials and eutherians (Fig. 4), the latter are also sometimes called “placental mammals” which is a misnomer because marsupials also have a placenta, though often a very brief and simple one. Among the three groups, the marsupials and eutherians are more closely related to each other than each of them are to monotremes (Fig. 3). For that reason, they are collectively called Theria. Monotremes are a small group of animals that, in many respects,

Fig. 3 Classification of mammalian placentas based on their gross morphological features. The distinctions are based on the shape and distribution of the specialized exchange structures on the surface of the fetal membrane.

Fig. 4 The major groups of mammals and the main stages in the evolution of mammalian female reproductive mode.

represent a mosaic of “reptilian” and therian characteristics. They consist of 14 extant species that come in two types, the echidnas and the platypus (Griffiths, 1978). They are also known as the “egg laying mammals.”

The differences in female reproductive biology between the three main groups of mammals can be read as a stepwise progression towards the more “advanced” eutherian form of reproduction. This view is certainly a simplification, since each lineage acquired their own characteristics and can thus not be considered generally “primitive” in any generalized way. Never the less, it is still true that some groups have retained ancestral features that underwent transformation and innovation in other groups. For instance, focusing on placentation, it is true that eutherians have a more elaborated fetal maternal communication, and the monotremes less so. In brief, monotremes lay eggs and incubate them until hatching, remotely similar to reptilian reproduction. In marsupials the early embryo remains in the shell coat (colloquially called “egg shell”) for much of its intra-uterine development but then “hatch” within the uterus and attach to the uterine endometrium to form an epithelio-chorial placentation (Tyndale-Biscoe and Renfree,

1987). Attachment can be brief, like in the opossum (2–3 days) or somewhat extended, like in the more derived wallabies (8 days) (Selwood, 2000; Griffith et al., 2017), but most of the “fetal” growth phase is happening outside the uterus attached to the maternal nipple. The term fetal seems appropriate for marsupial neonates because of their early stage of development. For instance the new born marsupials generally do not have hind limbs. They only develop and grow during the extended postnatal nursing phase. Finally, the eutherian mammals are characterized by a more extended gestation and a complete reliance on placental nutrition during fetal development. Below we will give a slightly more detailed description of the fetal–maternal relationship for each of the three groups.

Monotremes

All mammals have much smaller eggs compared to their reptilian sisters (Griffiths, 1978; Renfree and Shaw, 2002). The eggs are smaller because they are endowed with less yolk than bird and reptilian eggs. This also applies to the otherwise more “reptilian” monotremes, which do lay eggs rather than giving birth to live neonates. Never the less, already in monotremes there is a partial reliance on uterine provisioning from the mother, where the conceptus takes up uterine secretions and increases substantially in size before the egg shell is formed around them. For that reason some researchers consider monotremes as having a placenta, although an odd form of placentation. The odd thing about them is that the eggshell is formed after a phase of placental nutrient transfer rather than the other way around as in marsupials. After laying the eggs are incubated for about 10 days, either in a depression of the abdomen or even a posterior facing pouch. After hatching the young are licking milk secretions out of the fur of the mother for up to 6 months. Monotremes have milk glands but no nipples, so that the milk is seeping into the fur, where it is taken up by the young monotremes. Hence monotremes, even though they superficially appear reptile like in their reproductive biology, they are far from a mere copy of the ancestral reptilian condition.

Marsupials

As mentioned above, marsupial reproduction is in some respects between the monotreme and the eutherian phenotypes, but this view is inaccurate because of the diversity of marsupials and their reproduction. There are 334 recognized extant species of marsupials (Hunsaker, 1977), which evolved a wide variety of reproductive modes (Tyndale-Biscoe and Renfree, 1987). The deepest split within the marsupial tree is that between the American opossums and the Australian marsupials which make up 70% of the species diversity (Beck, 2008; Meredith et al., 2008). In the comparison between the opossums (Ameridelphia) and the Australian marsupials (Australidelphia) the opossums are more uniform and apparently more ancestral in many of their reproductive traits. The arguably ancestral characteristics include ovulation of multiple eggs, lack of maternal recognition of pregnancy, and a very short attachment phase (only 2 days in the gray short tailed opossum, *Monodelphis domestica*). In *Monodelphis*, the placental attachment leads to an inflammatory reaction on the side of the mother, which, in contrast to the situation in eutherians (see below), is increasing until it ends in parturition (Griffith et al., 2017). In contrast, the Australidelphia are more diverse and include groups which ovulate only a single egg and have definite recognition of pregnancy and a longer attachment phase, e.g., kangaroos and wallabies (Tyndale-Biscoe and Renfree, 1987).

In marsupials the conceptus spends a long time in the uterus surrounded in a shell coat, and only late in gestation dissolve it and attach to the lining of the uterus initiating a brief period of placentation. All placentation in marsupials is epitheliochorial, in the sense that there is no sustained contact between the trophoblast of the fetus and the connective tissue of the uterine endometrium. Nevertheless, the fetus seems to “attack” the uterine epithelium and, in opossum for instance, the trophoblast cells can penetrate between the epithelial cells of the luminal epithelium (Freyer et al., 2002). In rare occasions the trophoblast even can breach the basal membrane of the epithelium, but only very briefly before birth. In bandicoots (*Perameles*) the fetal trophoblast cells and the maternal uterine epithelial cells fuse and form a so-called “heterokaryons,” that are cells that contain nuclei from two different individuals, the fetus and the mother (Padykula and Taylor, 1976).

Placental structures are predominantly yolk sac derived with no contribution from the allantois. Only three families of marsupials have been reported to develop a choiroallantoic placenta, in addition to the yolk sac placenta. These are wombats, the koalas (Phalcolarctidae) and bandicoots (Peramelidae) (Freyer et al., 2003).

Eutherians

The pregnancy and placentation of eutherians is characterized by an earlier attachment and implantation of the blastocyst and a much longer sustained integration of fetal and maternal tissues (placentation) than in marsupials. That is to say that the absolute length of gestation is not necessarily longer, for instance the house (laboratory) mouse with 19–21 days of gestation has a shorter gestation time than wallaby with 28 days, but it is true that the gestation length of some eutherians can be much longer than any marsupial, up to 22 months as in elephants. Hence eutherians have evolved the ability to sustain fetal attachment and implantation for a very long time. This feature is associated with a much more intimate relationship between the fetus and the mother, although the exact anatomical and histological structures involved are highly variable between eutherian groups. Also, eutherians rely much more on allantois derived placental structures than marsupials. When yolk sack contributions to the placenta do occur, they play a much smaller role than they do in marsupials. Placentation through the yolk sack are usually found in early stages of pregnancy.

Contrary to the consensus in the 20th century, molecular mammalian phylogenies together with ancestral character state reconstructions have shown that the most recent common ancestor of eutherian likely had invasive placentation (Mess and Carter, 2006; Wildman et al., 2006; Martin, 2008; Elliot and Crespi, 2009). The classical model was based on the intuitively appealing model that epithelio-chorial → endothelio-chorial → hemo-chorial placentation seems like a natural progression. While this progression may have happened in the stem lineage of eutherian mammals, the most recent common ancestor of crown eutherians most likely had a form of invasive placentation. The exact form of placentation in the ancestor is not clear but the consensus view is that it was not epithelio-chorial. This model implies that the eutherian groups with less invasive placentation, epitheliochorial placenta, as seen in hoofed animals and their relatives, as well as galagos and dugongs must have evolved a less invasive placentation secondarily.

Even though hoofed animals together with their relatives (whales and dolphins) are classified as having an epithelio-chorial placenta and are thus grouped together with marsupials, the cow, horse and sheep placentas are not just a re-evolution of the transient, noninvasive placenta found in marsupials. Reevolving a less invasive placentation type, the so-called “ungulates” have evolved a number of unique specializations that make their placenta quite complex. As examples we will briefly review the situation in cows.

The uterus of the cow and related animals has specialized structures in their endometrium called caruncles. These are areas where the endometrial surface is highly folded forming either a convex or a concave structure. During pregnancy the trophoblast of the fetus forms projections that inter-digitate with the caruncular folds and thus forms a structure called cotyledon. Together the caruncle and the cotyledon form a placentome, which is the primary locus of exchange between the mother and the fetus. The number and size of placentomes varies between species between three to eight large ones in deer to as many as 150 in cows, goats and sheep. Within the placentome the uterine and fetal epithelia separate in certain places and accumulate stagnant maternal blood. These areas are called “hemophagous” zones because the trophoblast cells in these zones specialize in phagocytosing red blood cells and digest them to harvest the iron for the generation of fetal blood. Another cellular specialization of the trophoblast in the cotyledon is the development of binuclear cells (BNC) which play a role in the hormonal communication between the fetus and the mother. The BNC fuse with epithelial cell of the endometrium forming transient tri-nuclear cells. With the TNC the trophoblast cells can deliver hormones directly into the maternal endometrium without having to be taken up or let through by the luminal epithelium.

The areas of the trophoblast between the cotyledons have additional specializations, called areole. Areole form opposite to the openings of the uterine glands and are specialized for the resorption of the secretions of the uterine glands. These secretions are called “uterine milk” and is an alternative pathway for passing nutrients and antibodies from the mother to the fetus. The other pathway, of course, is the diffusion or active transport from the maternal blood to the fetal circulation at the placentome.

Hemochorial placentation, the primitive condition in eutherians, can be quite differently realized in different lineages. In most cases the development of a hemochorial placenta is accomplished through broad destruction of the endometrium and the maternal blood vessels. There are, however, exceptions. For instance placentation in armadillo and ant eaters is classified as hemochorial, which is technically correct as the placental villi are floating directly in the maternal blood. But this configuration is achieved with minimal tissue destruction. The placenta penetrates the endometrium at focal places, the villi grow down into the endometrium and finally ramify within materially provided blood sinuses. The armadillo endometrium has performed enlargements of the blood vessels at the fundus of the uterus. This mode of hemochorial placentation is quite different from the way hemochorial placentation is achieved in primates or rodents.

Decidua The mucosal lining during pregnancy

EVT Extra villous trophoblast, invasive in nature

GOS The great obstetric syndromes, collection of syndromes caused by poor placentation

HLA Human leukocyte antigen

KIR Killer immunoglobulin-like receptor

Preeclampsia A pregnancy complication presenting with diverse symptoms including hypertension

Introduction

The presence of unusual granulated cells in the uterine mucosa has been recognized for > 100 years ([Marchand, 1895](#)). The cells were first believed to originate from stromal cells but, with the advent of immunohistochemistry, it was realized that they belong to the hematopoietic lineage ([Bulmer and Sunderland, 1984](#)). Uterine NK cells are not simply NK cells found in the uterus. NK cells in the peripheral blood (pbNK cells) were identified 40 years ago and were named because of their innate and *natural* ability to kill certain leukemic cell lines without the prior sensitization needed for killing by cytotoxic CD8⁺ T cells. Uterine NK cells however, are poor killers of the same cell lines unless they are first activated in vitro ([King et al., 1989a](#)). It seems likely that uNK cells belong to the family of innate lymphoid cells (ILCs) that includes blood and tissue NK cells. ILCs primarily perform regulatory functions via release of mediators. Regrettably, a view that uterine NK cells can kill the embryo, and therefore need suppressing for a successful pregnancy to occur, has become widespread amongst many clinicians. Uterine NK cells are only in contact with placental trophoblast cells and not with somatic cells of the embryo and are unable to kill trophoblast without prior activation in vitro. If uNK cells were discovered today they would have been given a less tainted name, for example, uterine innate lymphoid cells.

Uterine NK cells are relevant to study because:

- they are the major population of lymphocytes present in the secretory endometrium at the time of implantation and in early decidua (the uterine lining in pregnancy) during the first trimester
- studies indicate they produce soluble products that act to modulate the walls of the uterine spiral arteries
- they are in close contact with trophoblast cells during placentation ([Fig. 1](#))
- genetic variants of NK receptors and their ligands have been linked to pregnancy complications and birth weight

Fig. 1 Immunohistochemistry of human implantation site. HLA-G⁺ extra villous trophoblast (EVT) cells (*pink*) and CD56⁺ decidual NK cells (*brown*) are found in close proximity. Courtesy of Lucy Gardner.

Most research on uNK cells focuses on their role in implantation. The invasion of trophoblast cells into the decidua during placentation in the early stages of pregnancy is important to establish the supply of blood and nutrients to the developing conceptus. During this process of arterial transformation, extravillous trophoblast (EVT) cells home to the spiral arteries resulting in destruction of the smooth muscle cells of the media to be replaced by “fibrinoid” material (Loke and King, 1997). Endovascular EVT cells move down the arterial lumen so that they are lined by trophoblast and not by endothelial cells. Deep invasion into the inner part of the myometrium are characteristics of a normal pregnancy (Brosens et al., 2011). However, the highly invasive nature of EVT cells clearly needs to be regulated since implantation on a scar from a previous cesarean section, or in the fallopian tube, results in trophoblast cells invading unhindered (placenta percreta) (Moffett and Colucci, 2015). Thus, the decidua has a unique capability to control and regulate the invasion. This control can also be too efficient as is the case in conditions such as preeclampsia and fetal growth restriction, where spiral artery remodeling is insufficient (Brosens et al., 2011). What components of the decidua regulate trophoblast invasion? One candidate is the uNK cells that are found in high abundance in the decidua. This article will summarize what is known about uNK cell involvement in human reproduction.

Characteristics of Uterine NK Cells

Nonpregnant Endometrium

Uterine NK cells are lymphocytes that lack markers for T and B cells and do not express clonotypic receptors that have undergone somatic gene rearrangement, but express the cardinal NK cell marker CD56 (Moffett-King, 2002). In the nonpregnant uterus, uNK cells are found both in the deeper basalis layer and in the superficial functionalis layer of the endometrium (King et al., 1991). In the estrogen-dominated proliferative phase, CD56⁺ uNK are relatively small and agranular. Following ovulation and the formation of the progesterone-secreting corpus luteum, uNK cells proliferate vigorously and become larger and granulated. Classical uterine NK cells are absent both before menarche and after the menopause. This suggests a hormonal dependence, but uNK cells do not express receptors for estrogen or progesterone. Such receptors are however found on uterine stromal cells and, in response to progesterone, the stromal cells produce interleukin 15 (IL-15), a cytokine known to induce NK cell proliferation. If no embryo implants the corpus luteum involutes and progesterone levels wane, leading to a decrease in IL-15. Uterine NK cells in the late secretor phase just before menstrual breakdown undergo nuclear fragmentation reminiscent of dying cells (King et al., 1989b). However uNK cells from menstrual blood can be used as a source of uNK cells and are viable (Ivarsson et al., 2016). More analysis is needed on the exact differences in phenotype and function between such uNK cells and those isolated from other time-points during the menstrual cycle.

During Pregnancy

If an embryo implants, the corpus luteum (and eventually the placenta) continues to produce progesterone and IL-15 levels are maintained permitting uNK cells to continue to proliferate and become even more abundant. Whether there are differences in the density and morphology of uNK in the decidua basalis where implantation takes place, compared to the decidua parietalis that lines the rest of the uterus is suspected but not well-documented. Uterine NK cells can however be identified throughout the decidua and are also always present in ectopic foci of decidua such as in endometriotic lesions and in tubal pregnancy (Bulmer et al., 2009).

The depth of trophoblast invasion differs greatly between species, ranging from no invasion (epitheliochorial placentation), to the very invasive placentation (hemochorial placentation) seen in humans. Only species with invading trophoblast cells have decidua and uNK cells, and a more invasive placentation correlates with increased decidualization of the uterine mucosa, again suggesting uNK cells perform a regulatory role to ensure a balanced invasion takes place (Moffett and Loke, 2006). During the first trimester of pregnancy the uNK cells persist in high numbers but towards term the number decreases with only a few cells still present. Uterine NK cells often have a distinct reniform shape and contain fewer but larger granules than pbNK cells. In spite of their granule content uNK cells are poor killers when measured in classic NK cell assays, as well as when they are cultured with trophoblast cells. Moreover, no reliable evidence of trophoblast killing by uNK cells *in vivo* has been reported. Instead regulatory functions during implantation are believed to be more important (discussed more below).

Detailed Phenotype of uNK as Defined by Flow Cytometry

Using modern flow cytometry techniques and different markers, the cells can be identified as CD45⁺ cells expressing CD56 in the absence of lineage markers (CD3, CD19, and CD14) for other leukocytes. Although both uNK cells and pbNK cells express CD56, uNK cells are CD56^{superbright} whereas pbNK cells can be either CD56^{bright} or CD56^{dim} (Moffett-King, 2002). Furthermore, uNK cells express combinations of NK cell receptors NKG2A, NKG2C, NKG2D, KIRs, LILRB1 and tissue-residency markers such as CD9, CD103, and CD49a. The activating receptors CD16 and DNAM-1 are found only on pbNK cells and not on uNK cells (Table 1). Some markers expressed by both uNK cells and pbNK cells differ in function. On pbNK cells the natural cytotoxicity receptors (NCRs) NKp30, NKp44 and NKp46 are all activating, but on uNK cells NKp30 is expressed as an inhibitory variant and NKp44 is only upregulated after activation *in vitro*. This NK receptor profile probably explains why uNK cells are poorly cytotoxic in cell–cell interactions. Similarly, adhesion receptor 2B4 is the same on the cell surface of pbNK cells and uNK cells, but it is missing its intracellular activating adaptor molecule (SAP) in uNK cells (Jabrane-Ferrat and Siewiera, 2014). In terms of granule content both uNK cells and pbNK cells (in particular CD56^{dim} pbNK cells) contain granules with similar types of preformed cytolytic molecules including perforin, granzymes, and granzylins. The functions of these granular molecules are unknown in uNK cells

Table 1 Summary of key surface markers and functional features that distinguish resting uterine NK cells from peripheral blood NK cell subsets

Receptor/property	uNK cells	pbNK cells	
CD56	Superbright	Bright (10% of NK cells)	Dim (90% of NK cells)
CD16	—	—	+
KIR	++/—	—	+/—
LILRB1	+/—	—	+/—
NKG2A	+	+	+/—
NKG2C	Low	+/—	+/—
CD9	+	—	—
CD103	+	—	—
CD49a	+	—	—
CD69	+	—	—
DNAM-1	—	+	+
CD57	—	—	+/—
Cytotoxic	—	+	+++
Cytokine production	+	++	+

but do indicate that they have the potential to kill if, for example, any NKG2D ligands were pathologically expressed by trophoblast. Gene expression arrays have identified several hundred genes that are differentially expressed between uNK cells and pbNK cell subsets (Koopman et al., 2003). Only recently have modern cytometry tools been implemented to study uNK cells and much remains to be understood about their phenotype and function in the nonpregnant and pregnant uterus.

Uterine NK Cell Development and Differentiation

Peripheral blood NK cells progenitors can be found in bone marrow as well as in secondary lymphoid tissue and liver. How uNK cell development is related to the development of pbNK cells is still unknown but three nonmutually exclusive theories have been proposed: First, a uNK cell precursor may be recruited from the blood which, upon entering the endometrium, differentiates into uNK cells. Second, a tissue-resident uNK cell precursor (possibly similar to the pbNK cell progenitor) may exist in the basal layer. This precursor would remain in the tissue throughout the menstrual cycle and respond to the sex hormones including progesterone, via IL-15 produced by stromal cells. Finally, pbNK cells may be recruited to the endometrium and decidua and there undergo changes in phenotype and function. More studies are needed before a consensus model of uNK cell development can be presented but whatever their origin, uNK cells do proliferate and differentiate in the unique hormonally induced microenvironment of the uterine mucosa (Vacca et al., 2011).

The Function of Uterine NK Cells

Nonpregnant Endometrium

What initiates menstruation is not fully understood but the first change in the morphology of the endometrium just prior to breakdown is the particular nuclear appearance of uNK cells. The nuclei are normally reniform but appear to fragment giving a superficial similarity to neutrophils—this is why they were called “endometrial granulocytes.” Because of their hormonal dependence and presence in the mucosa only during reproductive life, uNK cells are most likely involved in mucosal homeostasis, rather than in immune defense. (Classical T and B cells responses to infections can occur in the endometrium. The pathology of endometritis is characterized by the presence of abundant plasma cells and expansion of the small lymphoid follicles in the basal layer into germinal centers. Systemic infection by Mycobacteria TB can also result in classical endometrial granulomas.) It is thus possible that the angiogenic factors that uNK cells produce maintain the integrity of the arterial walls and when this is lost premenstrually breakdown ensues (King et al., 1989b). If pregnancy occurs the decidualization process of stromal cells that begins during the luteal phase of the menstrual cycle in the periarial regions (Streeter’s columns) continues. Part of the decidualization process is the change in the appearance of the media with loosening of the thick-walled muscle layer. The encircling of the arteries by uNK and their production of angiogenic mediators makes it likely that they contribute to the initial changes in the blood flow through these spiral arteries. Furthermore, uNK are also abundant beneath the basement membrane of the glands and secretion of factors such as epidermal growth factor (EGF) may contribute to the hypersecretory pregnant state of the glands and the stage of histiotrophic nutrition before the hemochorial placenta is established.

KIR and HLA Genes in Reproduction

If maternal immune cells do recognize and respond to the implanting trophoblast the receptor/ligand interactions are crucial to establish. The products of HLA class I and class II genes are dominant ligands for both NK and T cells and function for them to

survey the health of cells. The HLA genes are highly variable between individuals and encode proteins expressed on the cell surface of most cells in the body. However, in reproduction HLA class I molecules seem to serve an additional purpose. Villous cyto- and syncytiotrophoblast cells that are in contact with maternal blood circulating through the intervillous space are all devoid of HLA molecules. They also lack other ligands for immune cell receptors and adhesion proteins, and are thus inert to the immune cells of the maternal blood. In contrast, the invading EVT cells display a selective range of HLA molecules: no HLA class II nor HLA-A or B molecules, but high levels of HLA-C, and the nonclassical HLA-E and G molecules (Moffett-King, 2002). HLA-E and G genes do not vary much between individuals (oligomorphic), whereas HLA-C genes are highly variable or polymorphic with at least one thousand alleles that encode several hundred functional proteins. The receptors that bind to HLA-C are members of the Killer Immunoglobulin-like gene family (KIR) that are mainly expressed by both pbNK and uNK. The specificity of KIR for HLA-C depends on a dimorphism of two amino acids in the HLA-C sequence, which creates the C1 + HLA-C and C2 + HLA-C groups. KIR can impart either an activating or inhibitory signal to the NK cell depending on the length of the cytoplasmic tail, Long or Short. Inhibitory KIR2DL1 and activating KIR2DS1 bind C2 + HLA-C molecules, whereas inhibitory KIR2DL2/3 bind C1 + HLA-C. One set of HLA genes is inherited from each parent and a given individual therefore can be homozygous or heterozygous for C1 + or C2 + HLA-C. The KIR gene complex is also highly individual both in terms of gene numbers and allelic variation. The genes are inherited as two main KIR haplotypes, KIR A and KIR B, that can be used in genetic epidemiological studies to study disease associations. KIR A haplotypes contain only inhibitory KIRs (except KIR2DS4), whereas KIR B haplotypes contain additional activating KIRs (Fig. 2). Similar to HLA-C, an individual inherits KIR genes from both parents, and can therefore be KIR AA, AB, or BB. NK cells in KIR AA women will thus have no activating KIR compared to KIR AB or BB women. Because trophoblast cells are fetal in origin and will contain a mix of maternal and paternal genes, each pregnancy will be unique in terms of maternal KIR and fetal HLA-C genotypes (Moffett and Colucci, 2015).

When the KIR and C1 + or C2 + HLA-C genetic variants in mothers and their babies are genotyped and compared between those with normal pregnancies and those with pregnancy disorders, a role for uNK cells emerges. The Great Obstetric Syndromes (GOS) define pregnancy disorders associated with defective placentation, including preeclampsia (PE), stillbirth and fetal growth restriction (FGR), conditions associated with low birth weight. If the mother has a KIR AA genotype (meaning no activating KIR including the KIR2DS1 gene is present, Fig. 2), and the fetus carries a C2 + HLA inherited from the father, the pregnancy is at increased risk for PE (Fig. 3). Mothers carrying at least one KIR B haplotype (with the activating KIR2DS1 gene) are more likely to be protected from PE and FGR. In fact, the presence of a KIR2DS1 gene in combination with the fetus carrying paternal C2 + HLA increases the birth weight on average 200 g. This can be compared to the 50 g difference in birth weight seen between boys and girls. However, mothers with babies who are very large are at increased risk of obstructive labor, fistulae formation and fetal hypoxia. Notably, KIR BB mothers that carry multiple copies of KIR2DS1 are over-represented in pregnancies with such complications (Moffett et al., 2015).

How can these genetic findings be translated into uNK functions at the placental-uterine interface in the first trimester? If uNK cells are stimulated through KIR2DS1 in vitro, increased production of a range of soluble factors including granulocyte macrophage colony-stimulating factor (GM-CSF) occurs. EVT cells express the receptor for GM-CSF and when primary EVT cells are exposed to

Fig. 2 Representative KIR A and B haplotypes of the KIR gene family, together with their known HLA-C binding specificities (C1 and C2) depicted above their cognate KIR receptors. KIR2DS4 binds a limited number of C1 and C2 allotypes. Activating KIR are shown as blue boxes, inhibitory KIR are shown in red. Framework KIR genes that are present in all haplotypes are shown in black. Note that many of the KIR shown on the B haplotype are not present in all individuals. Reproduced from Moffett, A., Hiby, S. E. and Sharkey, A. M. (2015). The role of the maternal immune system in the regulation of human birthweight. *Philosophical Transactions of the Royal Society of London. Series B, Biological Sciences* **370** (1663).

Fig. 3 Presence of KIR B is associated with increased birthweight. Distribution of birthweights in the Norwegian MoBa cohort correlates with increased neonatal morbidity. Adaptation of figure from Moffett, A., Hiby, S. E. and Sharkey, A. M. (2015). The role of the maternal immune system in the regulation of human birthweight. *Philosophical Transactions of the Royal Society of London. Series B, Biological Sciences* **370** (1663).

GM-CSF they are attracted towards its source (Xiong et al., 2013). This offers proof of principle for how activating KIR2DS1 genes influence trophoblast behavior (invasion) in a favorable manner: In the presence of C2 + HLA on EVT cells, uNK cells expressing KIR2DS1 can bind to it and be activated. By contrast, in KIR AA mothers (with no KIR2DS1), this interaction cannot take place and the EVT cells are more likely to invade insufficiently. Importantly, many women with KIR AA genotypes do reproduce normally meaning activating KIRs are not essential for human reproduction. Instead, it is possible other activating receptors yet to be identified are expressed by all uNK cells, and that this basal activation is triggered by interaction between any uNK cell and EVT cells. This basal activation may contribute to the general EVT invasion, on top of which the KIRs fine tune and balance the degree of invasion.

KIRs are expressed both on pbNK cells in the peripheral blood of women, and on uNK cells. The KIR repertoire on uNK cells is different from that on pbNK cells, both in the nonpregnant uterus (Ivarsson et al., 2016) and in the pregnant uterus (Sharkey et al., 2015) with a much higher proportion of CD56⁺ uNK expressing KIR specific for HLA-C (KIR2DL1/S1 and KIR2DL2/L3) than found on pbNK in the same woman. Moreover, the KIR repertoire on pbNK cells is stable with time, and the repertoire on uNK cells is recapitulated each menstrual cycle. This indicates that each woman follows a unique uNK cell KIR acquisition program. How the uNK cell KIR repertoire in the nonpregnant uterus is related to that on uNK cells in the decidua during early pregnancy remains unknown but is relevant to study because of the implications the KIR receptors have, as discussed above.

Other receptors may also be involved in interaction of uNK with EVT. Similar to KIR, LILRB1, expressed by < 40% of uNK cells, is a strong inhibitory receptor that binds all HLA class I molecules and has a particularly strong affinity for the homodimer of HLA-G that is uniquely expressed by EVT cells (Jabrane-Ferrat and Siewiera, 2014). The inhibitory NKG2A receptor is highly expressed by up to 95% of uNK cells, and so is its activating counterpart NKG2C, albeit at much lower levels (Ivarsson et al., 2016). They both bind the nonclassical HLA-E ligand, which is expressed on EVT, where it forms a ligand for NKG2A/C. Up to 10% of some human populations lack a functional NKG2C gene, which may influence the function of uNK cells and in turn have consequences for pregnancy outcome similar to that seen for KIR2DS1 absence.

KIR receptors expressed on NK cells in other tissues and blood function in the detection and elimination of virally infected cells. Particular KIR/HLA genetic variants associate with resistance/susceptibility to a range of viruses. In general individuals with a combination of a KIR AA and C1 + HLA-C genotype are better at controlling viral infections. This is in contrast with protection from GOS associated with a maternal KIR B and fetal C2 + HLA-C genotype. This has led to the idea that the great variation in these two genetic families, KIR and HLA—known to be outliers in the extent of polymorphism—is balanced by the need for successful reproduction and survival from infection: If a virus epidemic strikes a population, individuals with C1 + HLA-C and KIR AA genotypes will be more likely to survive to reproductive age. Once the epidemic is over individuals with C2 + HLA-C and KIR B genotypes will be

Fig. 4 Model for the maintenance of KIR A and B haplotypes and HLA-C1 and C2 epitopes in human populations. With the onset of an epidemic with a lethal virus individuals with the protective C1 + HLA-C (HLA-C1) and KIR A haplotypes will be more resistance to infection, leading to selection of such individuals. At the end of the epidemic the survivors that carry C2 + HLA-C (HLA-C2) and KIR B will have larger and more robust progeny resulting in selection of HLA-C1 and KIR B. Adaptation of figure from Parham, P. and Moffett, A. (2013). Variable NK cell receptors and their MHC class I ligands in immunity, reproduction and human evolution. *Nature Reviews Immunology* **13** (2), 133–144.

able to reproduce better and will increase in frequency, until the next epidemic when the process may start again. Through human evolution this would result in the presence of C1 + and C2 + HLA-C, and KIR A and KIR B haplotypes individuals in all human populations, and this is indeed what is found (Parham and Moffett, 2013) (Fig. 4).

NK Cells and Fertility Tests

Many reports claim NK cells are dangerous in pregnancies and need suppressing to avoid killing the embryo but there is limited evidence for this view. As illustrated above a degree of uNK cell activity seems to be beneficial for pregnancy since it includes release of factors beneficial for implantation. Furthermore, uNK are phenotypically and functionally quite distinct from pbNK. Nevertheless, commercial blood tests that measure “NK cell numbers and activity” are offered to women at private infertility clinics. Women are then treated with a range of immunosuppressive drugs aimed at “suppressing” uNK activity. Future studies that link genetic, phenotypic, and functional data on uNK cells in large cohorts are needed if any form of useful NK cell tests are going to see the light of day (Moffett and Shreeve, 2015). Our understanding of their exact functional role in normal or disordered pregnancies is still very limited.

Summary and Future Perspectives

Since their discovery uNK cells have been suggested to influence pregnancy outcome via release of factors that act on the uterine arteries as well as invading trophoblast cells. Receptors expressed by uNK that have ligands on invading trophoblast cells have also been identified. Data supporting the importance of this interaction primarily comes from genetic studies, and insights into the cellular mechanisms are only beginning to emerge. The needed studies are limited by access to relevant study material such as endometrium and decidual tissue, and trophoblast cells. Acquiring primary trophoblast cells in sufficient numbers for in vitro studies is a limitation. A major stumbling block in the field is the lack of trophoblast stem cells in humans although these do exist in mice. The ability to perform in vitro studies is thus severely limited. The great heterogeneity afforded by KIR and HLA genes makes cohort studies of different tissue donors critical. Close collaborations between clinicians and immunologists are needed for this, as well as standardized methods to isolate and study uNK cells.

PREGNANCY

Endocrinology of Pregnancy

Megan S Johnson, Daniel L Jackson, and Danny J Schust, University of Missouri, Columbia, MO, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Beginning in the early first trimester, maternal physiology undergoes significant alterations. These adaptive changes must satisfy the fetal requirements for life while sustaining the maternal host. The placenta orchestrates many of these adaptations and is the site of complex interactions between the maternal and fetal endocrine systems. Not merely a conduit for the transfer of oxygen, nutrients, and waste products, the placenta functions dynamically as a new, transient endocrine organ as it utilizes precursors and substrates from the maternal and fetal compartments to synthesize new hormones (Pasqualini and Chetrite, 2016). Thus, the mother, placenta, and fetus express and respond to physiologic needs using an assembly of complex, bidirectional hormonal cascades as the mode of communication. In turn, the maternal–placental–fetal unit influences every endocrine axis throughout pregnancy, from conception to parturition. Many of these changes have direct implications in terms of prenatal care.

Establishment of Early Pregnancy

Maternal sex steroids alter the structure and function of the endometrium prior to implantation. Specifically, the endometrium undergoes cyclic changes in response to maternal estrogen and progesterone that enhance its receptivity to implantation in the early luteal phase of the menstrual cycle. If implantation occurs, the placenta and corpus luteum contribute changes essential to the maintenance of pregnancy.

Human chorionic gonadotropin (hCG) is the hormone used clinically to test for pregnancy. hCG is produced by the syncytiotrophoblast of the developing placenta and is responsible for maintaining the corpus luteum. The corpus luteum in turn produces progesterone to support development of the placenta. Early collapse of the corpus luteum leads to a drop in progesterone levels and pregnancy loss, whereas exogenous progesterone supplementation can prevent spontaneous abortion in select cases. It is for this reason that women with IVF pregnancies, in which the corpus lutei have been disrupted, require progesterone supplementation to maintain pregnancy until the 10th week of gestation. By this point, the placenta has predictably taken over progesterone production, and supplementation to recapitulate corpus luteal support is no longer required. A transient drop in maternal serum progesterone levels demonstrates this luteal–placental shift. Following this transition, the placenta, a new, temporary endocrine organ, becomes the primary source of pregnancy hormones, utilizing maternal and fetal precursors to produce an extensive array of proteins and steroids.

Placental Hormones

Human Chorionic Gonadotropin

Placental hCG shares structural homology with the pituitary hormones LH, FSH, and TSH. These protein hormones share a common alpha subunit but have distinct beta subunits that confer receptor specificity and thus biologic function. Still, hCG can also weakly interact with the receptors for these other pituitary protein hormones. Its luteotrophic effects can be seen in the stimulation of LH receptors of the corpus luteum, leading to progesterone production. Additionally, as hCG peaks in the first trimester, its binding to TSH receptors and subsequent thyroid stimulation leads to negative feedback that, in turn, causes a transient decrease in TSH levels.

As previously mentioned, embryonic production of hCG is crucial to early pregnancy. The early, rapid production of hCG coupled with its relatively long half-life (24 h) leads to a predictable, logarithmic increase in maternal serum levels of this hormone in normal pregnancy. The beta subunit of hCG can be detected in maternal urine or serum within 6–12 days following conception. Pregnancies that are outside the uterus (ectopic) or destined to end in miscarriage produce lower than normal levels of hCG, which manifests as a less than expected increase over a fixed, generally 48 h, time frame. Measurement of the beta subunit of hCG in maternal serum is frequently clinically useful. For instance, serial measurement of quantitative beta HCG (β hCG) is used in clinical practice to differentiate between viable intrauterine pregnancies and nonviable pregnancies, including ectopic pregnancies. Conversely, placental disorders such as hydatidiform moles tend to present with quantitative β hCG levels as much as 10-fold higher than the upper limit of that seen in normal pregnancies. In cases of hydatidiform moles or other

Fig. 1 Steroid hormone production by the maternal–placental–fetal unit. *DHEA-S*, Dehydroepiandrosterone sulfate; *16-OH-DS*, 16-Hydroxyl-dehydroepiandrosterone sulfate; *LH*, Luteinizing hormone; *FSH*, Follicle stimulating hormone.

trophoblastic disease, excessive β hCG levels can result in clinical thyrotoxicosis and thyroid storm due to the excessive cross-stimulation by hCG of TSH receptors.

Progesterone

Placental production of progesterone utilizes maternal cholesterol precursors (Fig. 1). The placenta lacks the enzymes (17 α -hydroxylase and 17,20-lyase) necessary to further convert progesterone to androgens, so the majority of progesterone is released from the placenta without further modification. Less than 10% of placental progesterone is transferred to the fetal compartment where it is converted to glucocorticoids and mineralocorticoids in the fetal adrenal glands. The remaining majority of placental progesterone (>90%) is released into the maternal circulation. Increased maternal progesterone leads to smooth muscle relaxation, affecting a wide range of maternal systems. Perhaps the most significant effect is the increased peripheral vasodilatation and resulting decrease in systemic vascular resistance (SVR) that occurs in normal pregnancy. This decrease in SVR is necessary to accommodate the expected 50% increase in maternal blood volume and is also associated with increased maternal cardiac output. Increases in maternal blood volume in pregnancy give delivering mothers a reserve to accommodate postpartum bleeding without cardiovascular collapse and could not be tolerated without the associated vasodilatation afforded by progesterone. Progesterone-mediated smooth muscle relaxation also contributes to ureteral dilatation, increasing risk of urinary tract infections, and esophageal sphincter relaxation, which, in combination with upward displacement of abdominal contents by the enlarging uterus, can lead to heartburn and gastroesophageal reflux disease (GERD). In the gallbladder, decreased smooth muscle contractility delays emptying and increases risk of maternal gallstones, while delayed bowel motility contributes to the nausea and constipation of pregnancy. Progesterone also

maintains uterine quiescence in human pregnancy by decreasing the expression of a number of genes related to myometrial contraction. Prostaglandin production is also inhibited by progesterone. Interestingly, a decrease in progesterone activity (and an increase in estrogen receptor expression) near term leads to parturition. Thus, progesterone supplementation in women at high risk of preterm birth delays parturition by preventing uterine contractions and maintaining cervical competence. Progesterone is therefore essential to many of the underlying physiologic changes necessary to support pregnancy and delivery. An understanding of these physiologic changes and their impact on maternal disease processes is essential to providing medical care for pregnant women.

Estrogen

Maternal serum estrogen levels rapidly increase early in pregnancy and peak at term, and the placenta is the major source of production. As mentioned above, the placenta lacks the necessary enzymes to convert cholesterol precursors into androgens. In a dramatic demonstration of maternal–fetal–placental interplay, androgens are supplied to the placenta from both the maternal and fetal adrenal glands and the fetal liver (Fig. 1). Placental aromatase then converts these androgen substrates (DHEA-S, 16-OH-DS) into estrogens, namely estrone, estradiol, and estriol. Estriol is essentially unique to pregnancy and serves as the major estrogen in maternal circulation during gestation. Because of this unique physiologic role and the fact that it is produced from fetal precursors, estriol has been studied as a surrogate marker of fetal well-being. Estriol levels are also used clinically as a component of prenatal screening for fetal aneuploidy.

Estrogens serve numerous physiologic roles during pregnancy. Through negative feedback on the anterior pituitary, estrogen ensures maternal resources will be devoted to the current pregnancy by suppressing FSH and LH production, thereby preventing development of additional ovarian follicles. Estrogen's major role in pregnancy is that of a trophic factor for both maternal and fetal tissues. Importantly, estrogens are responsible for growth of maternal organs, for example, enlargement of the uterus, expansion of pancreatic beta cell mass, and development of lactiferous glands and ducts in the breasts. Estrogens enhance several protective barriers in the pregnant woman, including formation of the "mucus plug" through cervical gland hypertrophy and mucin secretion, and reductions in vaginal pH through estrogen-mediated proliferation of vaginal lactobacilli. In concert with progesterone, estrogens increase uteroplacental blood flow through vascular proliferation, remodeling, and vasodilation, thus creating the low-resistance system crucial to ensuring adequate transfer of oxygen and nutrients to the growing fetus. Estrogens' trophic effects extend to fetal tissues as well, facilitating the maturation of fetal lung, liver, intestines, and CNS.

Human Placental Lactogen

Human placental lactogen (hPL) is a placental protein hormone secreted by the syncytiotrophoblast that rises steadily and peaks at 34 weeks of gestation. hPL shares structural homology with growth hormone (GH) and prolactin and can bind both receptors. In concert with human placental growth hormone (hPGH), hPL modulates maternal metabolism to meet the energy requirements of the developing fetus. Specifically, hPL and hPGH induce peripheral insulin resistance and thereby reduce maternal glucose utilization, while concomitantly increasing maternal lipolysis. The net result is an increased maternal reliance on fatty acids and ketones, leaving an abundant supply of glucose for the fetus. Increased fatty acids and ketones in the maternal circulation also serve as substrates for steroid hormone production by the placenta. Interestingly, insulin resistance and compensatory hyperinsulinemia resolve quickly after delivery, further affirming that these changes in maternal metabolism are driven specifically by diabetogenic placental hormones.

Thyroid Physiology During Pregnancy

Maternal Thyroid Physiology

Thyroid physiology changes dramatically in normal pregnancies. Under the influence of estrogen, the maternal liver increases production of thyroid-hormone-binding globulin (TBG), which sequesters free T3 and T4. This initiates a compensatory stimulation of thyroid hormone production driven by the hypothalamic–pituitary axis, and the thyroid gland enlarges by 15%–30%. As a result of these changes, total (free and TBG-bound) serum T3 and T4 levels increase in pregnancy, while free T3 and T4 remain unchanged or only marginally decrease. In the first trimester, the increased thyroid hormone production is uniquely driven by stimulation of the thyroid gland by the alpha subunit of placental hCG, which is structurally similar to TSH (Fig. 2). Following the 1st trimester, TSH steadily increases through gestation and peaks at term. Maternal peripheral thyroid hormone metabolism is also enhanced in pregnancy. The placenta expresses type II and type III deiodinases that, respectively, convert T4 into T3 and T3 into reverse T3. This process is essential to provide the necessary thyroxine for normal fetal brain development in the first trimester prior to the onset of fetal thyroid function.

Thyroid dysfunction is one of the most common complications of pregnancy and adversely affects fetal and maternal well-being, and an understanding of maternal thyroid physiology is essential to proper management.

Hypothyroidism in Pregnancy

Hypothyroidism affects about 2% of pregnancies and can result from iodine deficiency, autoimmune disease, drug induced hypothyroidism, or treatment for hyperthyroidism. The most common cause of hypothyroidism worldwide is iodine deficiency,

Fig. 2 Thyroid physiology during pregnancy. *bhCG*, Beta human chorionic gonadotropin; H_2O_2 , Hydrogen peroxide; *TPO*, Thyroid peroxidase; T_3 , Triiodothyronine; T_4 , Tetraiodothyronine; *TSH*, thyroid stimulating hormone.

although in the developed world where dietary iodine deficiency is rare, Hashimoto's disease is the most common underlying etiology. Hypothyroidism is diagnosed by elevated serum levels of TSH and low levels of T_4 (free or total corrected for pregnancy).

Normal fetal growth and development are dependent upon maternal thyroid hormone production and transport. While maternal TSH does not cross the placenta, maternal thyroxine does cross the placenta. In early gestation, maternal euthyroid status needs to be maintained to ensure that sufficient thyroid hormone, which is critical for the developing fetal brain, reaches the fetus. The fetal brain expresses thyroid hormone (TH) receptors in the first trimester. This is prior to the initiation of fetal thyroxine synthesis, which occurs at around 14 weeks of gestation. The critical period for brain development is therefore occurring during a time when thyroid hormone is exclusively supplied via the placenta from maternal-derived sources. Untreated maternal hypothyroidism is associated with decreased infant mental and motor function scores as well as lower IQ scores in childhood, and severe maternal hypothyroidism can lead to congenital cretinism characterized by growth failure and fetal cognitive and neuropsychological deficits. In fact, iodine deficiency, which affects > 30% of the global population, is the world's leading cause of preventable intellectual disabilities. Apart from fetal requirements, adequate thyroid function appears to also be necessary for healthy pregnancy. Pregnancies complicated by hypothyroidism are at risk for a number of adverse outcomes including preterm birth, preeclampsia, maternal anemia, placental abruption, low birth weight (Tong et al., 2016), and postpartum hemorrhage. In addition, antithyroid antibodies, such as those found in autoimmune thyroid disease, have been associated with early pregnancy loss and may even be a cause of recurrent pregnancy loss in some women (Smith and Schust, 2011).

Early diagnosis and management of hypothyroidism can minimize the risk of poor outcomes. While a recent, large metaanalysis demonstrated that universal thyroid function screening did not impact maternal and neonatal outcomes (Spencer et al., 2015), clinicians should have a low threshold for initiating testing in pregnant women with symptoms of hypothyroidism or a personal or family history of autoimmune endocrine disease. Unfortunately, the cluster of nonspecific symptoms that can accompany subclinical and even overt hypothyroidism (fatigue, lethargy, weight gain, cold intolerance, constipation, enlarged thyroid, hair loss, brittle nails, and dry skin) overlaps considerably with many normal pregnancy symptoms. The thyroid function of women with preexisting hypothyroidism should be tested at least each trimester, as replacement requirements increase throughout pregnancy and should be adjusted accordingly. Initial testing should include TSH levels, with free T_3 levels if TSH is found to be abnormal. Correct interpretation of thyroid function studies in pregnancy requires a thorough understanding of the normal physiologic changes that occur over the course of gestation. The recommended treatment for maternal hypothyroidism is oral levothyroxine.

Hyperthyroidism in Pregnancy

Hyperthyroidism, while less common in pregnancy than hypothyroidism, also places a burden on maternal physiology and can cause adverse pregnancy outcomes. Overt and subclinical hyperthyroidism complicate 1% of pregnancies. Prompt recognition and treatment are critical to prevent maternal and neonatal morbidity but can be complicated by the overlap of normal pregnancy symptoms and those of hyperthyroidism, including nausea/vomiting, heat intolerance, increased appetite, insomnia, fatigue, irritability or anxiety, and tachycardia. Weight loss, hypertension, tremor, eyelid lag, proptosis, and thyroid enlargement are symptoms

less common in pregnancy that may more directly suggest hyperthyroidism. Hyperthyroidism is characterized by a suppressed TSH and elevated levels of thyroxine. As in hypothyroidism, unadjusted serum free T3 and T4 levels, or total T3 and T4 levels corrected for pregnancy can be used for diagnostic purposes.

Subclinical hyperthyroidism in pregnancy is characterized by suppressed circulating TSH levels with free T3 and T4 in normal pregnancy ranges. A strong association between subclinical hyperthyroidism and adverse pregnancy outcomes has not been definitively established, though the presence of antithyroid antibodies in euthyroid women may be associated with early pregnancy loss (Thangaratinam et al., 2011). However, overt hyperthyroidism, with low TSH and high free T3 and T4 levels outside the normal pregnancy ranges, places pregnancies at risk for preterm labor, fetal growth restriction, stillbirth, preeclampsia, and maternal heart failure. Furthermore, fetal thyrotoxicosis caused by transplacental transfer of thyroid-stimulating antibodies may manifest as fetal tachycardia, fetal heart failure, nonimmune hydrops, and even fetal death.

By far the most common cause of hyperthyroidism in pregnancy is Graves' disease, which accounts for 90%–95% of cases and is mediated by maternal thyroid receptor-activating antibodies. It is important to distinguish Graves' disease from transient hyperthyroidism in early pregnancy, which does not require treatment. Transient hyperthyroidism of pregnancy results from hCG-mediated thyroid receptor activation. Although historically an evaluation for hyperthyroidism has been part of the evaluation for hyperemesis gravidarum, current guidelines do not support testing for hyperthyroidism in the setting of hyperemesis unless other signs or symptoms of hyperthyroidism are present. Treatment of transient hCG driven hyperthyroidism has not been shown to benefit maternal or fetal outcomes or improve symptoms of hyperemesis. Gestational trophoblastic disease can cause hyperthyroidism due to extremely high levels of hCG and cross-reactivity with the thyroid hormone receptor. Other uncommon causes of hyperthyroidism in pregnancy include thyroid nodules, toxic multinodular goiter, exogenous thyroid hormone exposure, thyroid cancer, ovarian teratomas with ectopic thyroid tissue (struma ovary), and pituitary tumors.

Regardless of the cause, overt hyperthyroidism and thyrotoxicosis require treatment to prevent maternal and neonatal morbidity. Thionamides prevent thyroid hormone synthesis by inhibiting thyroid peroxidase-mediated iodination of thyroglobulin tyrosine residues and are the mainstay of therapy in pregnancy. Both propylthiouracil (PTU) and methimazole cross the placenta and can cause congenital anomalies and fetal hypothyroidism, so in general the lowest dose of medication effective in treating maternal symptoms and resulting in biochemical maternal euthyroidism should be used. In particular, fetal exposure to methimazole in the first trimester is associated with fetal malformations such as choanal and esophageal atresia, facial anomalies, and aplasia cutis. For this reason, PTU, which further treats hyperthyroidism through inhibition of peripheral conversion from T4 to T3, is the recommended therapy during the first trimester. However, transition to methimazole is recommended for the second and third trimester to avoid the rare but serious risk of PTU-induced maternal hepatotoxicity. Both thionamides can cause leukopenia and, rarely, acute onset of agranulocytosis. Therefore, any evidence of maternal or fetal infection warrants a complete workup. Of note, radioactive ablation of the thyroid with I-131 is a mainstay of treatment in the nonpregnant population. This approach is absolutely contraindicated in pregnancy as it results in destruction of the fetal thyroid.

Women with overt hyperthyroidism are at risk for thyroid storm, which is a life threatening acute exacerbation of hyperthyroidism that can be triggered by infection, anemia, preeclampsia, labor, and vaginal or cesarean delivery. Thyroid storm is marked by a hypermetabolic state causing dysfunction in the following systems: thermoregulatory (hyperthermia), central nervous system (agitation, delirium, psychosis, coma), gastrointestinal (nausea, vomiting, diarrhea), hepatic (jaundice), and cardiovascular (tachycardia, pulmonary edema, arrhythmia). Immediate recognition and treatment is critical, and transfer to an intensive care unit and immediate consultation with physicians experienced in this condition can be life saving for both the mother and fetus. In crisis situations, high-dose thionamide therapy is initiated first, and iodine can be added after at least 1 h of stabilization to prevent release of T4. Beta blockers are often utilized to control maternal heart rate and further inhibit peripheral conversion of T4 to T3. Corticosteroids may also reduce this conversion and are thus an additional adjunct therapy. Delivery for nonreassuring fetal status should be delayed until the maternal condition has stabilized, as delivery can exacerbate thyroid storm.

Hypothalamic–Pituitary (–Adrenal) Axis Physiology

The anterior pituitary can double or triple in size during pregnancy. The increased mass is largely due to lactotroph hyperplasia and hypertrophy. Increases in maternal estrogens drive increased lactotroph production of prolactin, the levels of which rise throughout pregnancy. In contrast, pituitary somatotroph and gonadotroph size decreases in pregnancy, likely via negative feedback from placental-derived sex steroids; corticotroph and thyrotroph sizes remain unchanged. Pregnancy-related adaptations in pituitary function drive a number of alterations in HPA physiology.

Cortisol

Cortisol production and secretion from the adrenal cortex is stimulated by adrenocorticotrophic hormone (ACTH) from the anterior pituitary. ACTH is, in turn, under the control of corticotropin-releasing hormone (CRH) from the hypothalamus. Total and free plasma cortisol levels increase considerably during pregnancy, driven primarily by estrogen-mediated increases in hepatic production of cortisol-binding globulin. Increased pituitary ACTH secretion as well as increased adrenal responsiveness to ACTH also

contribute to the enhanced rate of cortisol synthesis. Additional CRH and ACTH are produced by the placenta. In contrast to the nonpregnant state in which cortisol exhibits negative feedback on CRH secretion from the hypothalamus and ACTH production in the pituitary, cortisol stimulates placental CRH in a feed-forward mechanism that continues throughout pregnancy. Although the resulting pregnancy-associated generation of increasingly elevated plasma free cortisol can reach levels approaching those seen in Cushing syndrome, the normal diurnal pattern of cortisol is maintained, and women do not typically exhibit symptoms of hypercortisolism. Interestingly, CRH interactions appear to play a role in determining timing of parturition ([Wadhwa et al., 1998](#)). Higher levels of maternal cortisol have been associated with increased risk of preterm delivery.

Aldosterone

Estrogen stimulates hepatic production of renin substrates, which initiates an upregulation of the renin–angiotensin–aldosterone system (RAAS). The subsequent rise in angiotensin II leads to an 8- to 10-fold increase in adrenal aldosterone production and a corresponding increase in maternal plasma aldosterone levels. These changes increase sodium and water retention and support maternal blood volume expansion. Consequent maternal hypertension is avoided due to decreased vascular sensitivity to angiotensin II. However, in the setting of gestational hypertension and preeclampsia, vascular resistance to angiotensin II does not occur and maternal hypertension ensues.

Androgens

The maternal adrenal gland is an important source of androgens in pregnancy, and adrenal production of DHEA and DHEA-sulfate doubles compared to the nonpregnant state ([Makieva et al., 2014](#)). Despite this, maternal serum levels remain at nonpregnant levels; the placenta utilizes the additional maternal androgens as substrates in estrogen production. Total circulating maternal testosterone levels rise in pregnancy, with the majority being bound by sex hormone binding globulin. The fetus serves as an additional source of DHEA, and thereby contributes to placental estrogen synthesis.

Hormonal Control of Glucose Regulation

Fetal Fuel Requirements Drive Alterations in Maternal Metabolism

Maternal glucose is the primary energy source for the fetus, and the maternal host is the sole provider of that fuel. Glucose transport to the fetus across the placenta is via facilitated diffusion through the sodium-independent transporter protein Glucose transporter 1. Beginning early in pregnancy, fetal metabolic requirements drive alterations in maternal insulin secretion and glucose metabolism. Notable changes include relative maternal hyperinsulinemia, insulin resistance, fasting hypoglycemia, postprandial hyperglycemia, and increased maternal plasma lipid concentrations. The net result is a shift in maternal metabolism toward fatty acid utilization, thereby preserving glucose for fetal use.

Maternal pancreatic beta cell mass expands by approximately 50% in pregnancy. Beta cell hyperplasia and hypertrophy are stimulated by estrogen, progesterone, and human placental lactogen and result in increased insulin secretory capacity. While basal insulin concentrations remain stable, secretion in response to food increases, resulting in a net hyperinsulinemic state in the pregnant mother. This is accompanied by relative insulin resistance and thus decreased insulin-mediated glucose transport to maternal tissues. Insulin resistance is mediated primarily by the placental hormones hPL and hPGH. Increased maternal cortisol, TNF- α , leptin, and decreased adiponectin also contribute to increased maternal insulin resistance. These physiologic changes confer insulin resistance through decreased insulin receptor tyrosine kinase autophosphorylation and a decrease in insulin signal transduction ([Friedman et al., 1999](#)). This is evidenced by altered expression of the insulin receptor downstream signaling molecules IRS-1, IRS-2, PI3-K, and GLUT-4 in women with gestational diabetes ([Colomiere et al., 2010](#)).

The net result of these changes is a unique physiologic state driven by placental hormones. Maternal insulin resistance increases, leading to increased peak glucose levels following meals. This is coupled with accelerated maternal lipolysis and increased maternal utilization of triglycerides, cholesterol and fatty acids. The end result is increased availability of glucose as an energy source for the fetus and placenta.

Gestational Diabetes

Insulin resistance peaks in the third trimester of pregnancy, and if the increase in insulin secretion is not commensurate, gestational diabetes (GDM) develops. Put another way, GDM manifests when increased maternal insulin secretion is not sufficient to counter the increased insulin resistance caused by placental hormones. Multiple sets of diagnostic criteria are used to diagnose GDM, and depending on whether one step or two step screening is used, the incidence in pregnancy ranges from 3% to 25%. Prevalence also varies according to ethnicity and increases with increasing maternal age. Women with GDM are at increased risk of urinary tract infections, pyelonephritis, hypertension, and preeclampsia. Pregnancies of women with GDM are also at risk of polyhydramnios, preterm delivery, and cesarean delivery. Fetal risks include macrosomia, intrauterine growth retardation (IUGR), stillbirth, birth injury, and, with poor glycemic control near the time of delivery, neonatal acidemia and hypoglycemia. Treatment of GDM reduces the risk of macrosomic infants, serious perinatal complications, and maternal hypertensive disorders ([Crowther et al., 2005](#); [Landon](#)

et al., 2009). Nutritional and lifestyle modifications are critical to this goal and can be effective interventions, but early transition to pharmacologic therapies is advised if dietary changes and exercise do not adequately control blood glucose values consistently. The American Diabetes Association and the American Congress of Obstetricians and Gynecologists recommend insulin over oral hypoglycemic agents as the first line treatment for gestational diabetes mellitus (GDM). The reason for this recommendation is that oral hypoglycemic agents such as metformin and glyburide cross the placenta, while insulin does not. There is some data to suggest that in utero exposure to oral hypoglycemics confers additional fetal risks beyond those seen in GDM. Neonatal outcomes are also improved with insulin use as compared to oral hypoglycemics. Women with GDM have up to 70% increased risk of type 2 diabetes mellitus (T2DM) later in life, with the common mechanism likely being increased baseline insulin resistance. Thus, women who had GDM should undergo postpartum screening for abnormal glucose metabolism.

Preexisting Diabetes in Pregnancy

Because the complications of GDM detailed above are related to suboptimal glycemic control, pregnancies in women with preexisting diabetes have similar risks. However, due to the earlier fetal exposure to potentially elevated glucose levels during embryogenesis, preexisting diabetes carries additional risks of spontaneous abortion and congenital anomalies of the cardiac and central nervous systems. As the diabetogenic placental hormones facilitate an environment of insulin resistance, insulin requirements for women with preexisting diabetes increase throughout pregnancy, and many women on oral hypoglycemic agents prior to pregnancy will need to transition to insulin therapy. Close blood sugar monitoring and aggressive pharmacological management is necessary to prevent complications and optimize conditions for delivery. An ultrasonographic assessment of fetal morphology at 20 weeks and fetal echocardiography at 24 weeks of gestation can detect most major fetal anomalies, and antepartum fetal surveillance recommendations are the same as in GDM. It is also noteworthy that the increased lipolysis and catabolism of fatty acids that occur in normal pregnancy predispose pregnant type I diabetics to the development of diabetic ketoacidosis (DKA), a life-threatening condition characterized by acidemia, hyperglycemia and profound dehydration and electrolyte abnormalities.

Maternal diabetes accounts for a substantial portion of stillbirth in the developed world. As such, women with pregestational diabetes and women with gestational diabetes requiring medical treatment undergo serial antenatal testing in the third trimester in an attempt to prevent stillbirth. Due to the increased risk of stillbirth, delivery is typically recommended at 39 weeks of gestation, with earlier delivery indicated in the setting of poor glycemic control.

Conclusion

Starting with early gestation and continuing through parturition, the maternal endocrine system undergoes profound alterations to facilitate implantation, growth, development, and delivery of a healthy neonate. These changes are generally beneficial to the developing fetus, but in the presence of underlying maternal comorbidities can occasionally be maladaptive. A thorough understanding of maternal endocrine changes is essential to the provision of quality prenatal care with the goal of optimizing maternal and fetal outcomes.

Introduction

Pregnancy leads to extensive changes in maternal physiology, which promote metabolic, cardiovascular and immunological adaptations critical for maintaining pregnancy and supporting fetal growth. The placenta is a transitory fetal organ that serves as the primary interface between the mother and the fetus, establishing an immunological barrier and performing critical functions such as production of pregnancy-related hormones and transport of nutrients and oxygen from the mother to the developing fetus. This chapter discusses the fetal-maternal unit by describing placental structure among mammalian species and concisely reviewing placental endocrine and transfer functions. The importance of the fetal membranes and decidua, which represent other sites where maternal and fetal tissues interact, will also be discussed.

Placental Unit

The placenta is a complex, transient organ that constitutes the primary interface between the mother and the fetus throughout pregnancy. It is formed after the implantation of the embryo in the uterine lining. Placental development involves complex cellular and molecular interactions between maternal and embryonic tissues such as cell proliferation and migration and immunomodulation. In mammals, placental morphology and structure varies but its function remains essentially the same in all species. The placenta performs a number of critical physiological, endocrinological and immunological functions, which are important to establish and maintain an optimal intrauterine environment for the development and growth of the fetus.

Diversity of the placental structure

The establishment of an intimate contact between mother and embryo in early pregnancy is followed by critical steps of placental development with varying timing between species. The structure of the placenta is also dependent on the anatomical structure of the uterus which differs among mammalian species. There are three main types of uteri: (a) double uterus: with two cervixes and two independent uterine horns, found in rodents; (b) bicornuate uterus: with one cervix, one uterine body and two communicating uterine horns, found in ruminants, and carnivores; (c) simplex uterus: with one cervix and one uterine body without uterine horns, found in primates and bats (Chavatte-Palmer and Tarrade, 2016).

The placenta can be classified based on morphology, histological structure and interdigitation of the feto-maternal interface (Fig. 1) (Furukawa, S. et al. (2014), Enders and Blankenship, 1999). Based on gross shape or on the distribution of the feto-maternal exchange surface area that covers the chorionic sac enclosing the fetus, four main types of placenta are recognized: (i) diffuse: covers the entire surface of the uterine epithelium, found in pigs and horses; (ii) multi-cotyledonary: characterized by distinct placental regions or cotyledons occupying the entire surface of the endometrium, found in ruminants; (iii) zonary: feto-maternal exchange zone that forms a belt around the chorionic sac, found in carnivores; (Sobrevia, L. et al.) bidiscoid/discoid: characterized by a single or double disc where the maternal-fetal exchange area is confined to a circular or oval area, found in primates, rodents and humans (Chavatte-Palmer and Tarrade, 2016).

Based on the histology of the feto-maternal interface, the three main placental types are epitheliochorial, endotheliochorial and hemochorial. *Epitheliochorial interface* is the most superficial and lacks significant invasion of the uterine lining by trophoblast cells. No loss or invasion of the maternal tissues occurs and no cell layers are removed. There are three maternal layers (vascular endothelium, uterine connective tissue, uterine epithelium) and three fetal layers (vascular endothelium, fetal connective tissue and trophoblast) that separate maternal and fetal blood supplies. In the *endotheliochorial interface*, two maternal cell layers (uterine epithelium and connective tissue) are removed after implantation. The maternal vascular endothelium remains and comes into direct contact with the trophoblast cells, fetal connective tissue and fetal endothelium. The *hemochorial placenta*, is the most invasive type and all three cell maternal layers (vascular endothelium, uterine connective tissue and uterine epithelium) disappear, allowing direct contact between the maternal blood and the syncytiotrophoblast. Hemochorial placenta can also be classified based on the number of trophoblast layers; namely hemodichorial (two trophoblast layers) which is the case for rabbits and hemotrichorial (three trophoblast cell layers) in rats and mice. The human placenta is hemochorial, where a single trophoblast layer (the syncytiotrophoblast) constitutes the primary barrier between maternal blood in the intervillous space and the fetal capillary endothelium.

The number of cell layers in the feto-maternal interface influences placental transfer efficiency for example, the ability of molecules to cross the placenta in either direction is affected by the distance or thickness of the cellular barrier between maternal and fetal blood. An invasive type of placenta such as the hemochorial placenta of rodents and primates, with a minimal number of cell layers between maternal and fetal circulations, is characterized by an efficient exchange.

Placentas are also classified based on their interdigitation: (i) folded: is the simplest form and is characterized by small folds that interlock with corresponding endometrial folds (Hafez, 2017); (ii) lamellar: a more extensive array of branched folds that increase adherence and facilitate exchange by increasing the surface area; (iii) villous: trophoblast projections form tree-like highly branched

Representative Species	Pregnancy Length (Days)	Placental Morphology	Placental Interdigitation	Feto-Maternal Interface
	308-336	 Diffuse Cover over the entire surface of the uterine luminal epithelium with formation of folds/villi.	 Horse (a)	 Epitheliochorial Most superficial placenta with lack of significant invasion of the maternal tissues. No maternal layers or connective tissue are removed. Three maternal and three fetal layers are present. Synepitheliochorial is used to describe to placenta of ruminants. Trophoblasts (binucleate cells) fuse with a single uterine epithelial cell, giving rise to trinucleate cells or multinucleate structures of mixed fetal and maternal origin.
	115-122		 Pig (b) (a) Villous Chorion forms tree-like villi which interdigitate into corresponding endometrial folds. (b) Folded Chorion forms simple small folds that interlock with corresponding endometrial folds.	
	279-287	 Multi/Cotyledonary Characterized by distinct placental regions of the endometrium, also known as caruncles. These caruncles are protuberances in the uterine wall with vascular adaptations to establish fetomaternal interface.	 Villous Chorion forms tree-like villi which interdigitate into corresponding endometrial folds.	
	152			
	150			
	504-616	 Zonary Intimate interdigitating contact zone that forms a belt around the chorionic sac.	 (a)	 Endotheliochorial Maternal uterine epithelium and connective tissue disappear after implantation. Fetal chorionic epithelium comes into direct contact with maternal endometrium epithelium.
	93-112		 (b)	
	58-68		(a) Lamellar More extensive array of branched folds that increase adherence and facilitate exchange. (b) Labyrinthine Maternal blood circulates between the syncytiotrophoblast.	
	259-280	 Bidiscoid/Discoide Characterized by single or double disc. Interaction is confined to the circular area.	 Villous Chorion forms tree-like villi which interdigitate into corresponding endometrial folds.	 Hemochorial The most invasive. Maternal connective tissue layers disappear leading to direct contact between chorionic epithelium and maternal blood.

Fig. 1 Classification of the placenta by morphology, interdigitation and interface histology in *representative species*. FC, fetal capillary; CE, chorionic epithelium; BM, basement membrane; UE, uterine epithelium; MC, maternal capillary; Cy, cytotrophoblast; Sy, syncytiotrophoblast; MB, maternal blood.

villi which interdigitate into endometrial folds; (Sobrevia, L. *et al.*) labyrinthine: is the most structurally elaborate type, with trophoblast projections interconnected in a web-like structure, leaving narrow channels for maternal blood flow.

Functions of the placenta

Endocrine

The placenta secretes hormones and other signaling molecules to the maternal circulation, which are critical for the establishment and maintenance of pregnancy by regulating the maternal physiological adaptations to pregnancy, and to the fetus, which promote fetal development and growth (Costa, 2016). In addition, placental hormones are believed to play a role not only in placental development but also the initiation of labor and breast feeding (Costa, 2016). Abnormal production of placental hormones may contribute to the development of pregnancy complications such as preeclampsia. Hormones are synthesized and secreted by the trophoblast and its concentration vary widely between species. The major source of hormone production is the syncytiotrophoblast — a differentiated multinucleated subtype of trophoblast with no proliferative capacity and in intimate contact with maternal blood in the case of hemochorial placentas.

Steroids hormones are one important class of molecules secreted by the placenta. Progesterone, synthesized from maternal cholesterol in the syncytiotrophoblast mitochondria, is required for successful embryo attachment and implantation and essential to maintain pregnancy (Halasz and Szekeres-Bartho, 2013). Progesterone contributes to immune-tolerance by suppressing the maternal cell-mediated immunity to prevent rejection of the fetus, inhibits myometrial contractility and promotes uterine quiescence throughout pregnancy (Romero *et al.*, 2014, Ruddock *et al.*, 2008). Circulating maternal progesterone concentrations increase throughout pregnancy and decrease following labor and placental delivery. In addition, progesterone prepares the mammary gland for lactation by enhancing its proliferation and prevents lactation until labor.

Estrogens such as estrone (E₁), 17 β -estradiol (E₂), estriol (E₃) and esterol (E₄) are synthesized by the placenta. Maternal serum estrogen concentrations increase profoundly during pregnancy, peaking at term. Estradiol is the most abundant estrogen, which has an array of functions in pregnancy, such as promoting receptor-mediated uptake of LDL cholesterol for placental steroid production, increasing uteroplacental blood flow and preparing breast tissue for lactation by increasing prolactin synthesis and secretion (Corcoran *et al.*, 2014). In addition, estradiol is involved in labor as it promotes myometrial contractility. Moreover, estradiol stimulates the proliferation of the mammary gland preparing this tissue for breastfeeding and it is involved in maternal metabolic changes such as promoting insulin biosynthesis, hyperlipidemia, fat storage and inhibits lipolysis (Hur *et al.*, 2017).

The placenta secretes polypeptide hormones such as human chorionic gonadotropin (hCG), which is detectable in maternal blood as early as two days after implantation and is utilized in most common pregnancy tests. There are five independent variants of hCG, they all share a common α -subunit and a distinct β -subunit that confers specificity. hCG has multiple functions during pregnancy such as promotion of angiogenesis in the uterine vasculature, maintaining quiescence of the myometrium and contributing to the immunotolerance at the fetal-maternal interface (Fournier *et al.*, 2015). The syncytiotrophoblast is the main source of hCG. A unique function of hCG is to maintain the secretion of progesterone and estradiol from the corpus luteum during the first 6 weeks of pregnancy. In addition, hCG promotes the fusion and differentiation of cytotrophoblast to syncytiotrophoblast cells and thus generating the villous trophoblastic layer that characterizes the hemochorial placentation in humans (Cole, 2012). Total hCG concentration in the maternal circulation increases rapidly during the first trimester, reaches highest concentration at 10 weeks of gestation and declines slowly until term.

Human placental lactogen (hPL), also known as chorionic somatomammotropin, is a polypeptide hormone that is mainly synthesized by the syncytiotrophoblast. It is detected in maternal circulation after 3–6 weeks of gestation, increases throughout gestation and disappears after placental delivery. The main functions of hPL are the regulation of maternal lipid and carbohydrate metabolism and it may contribute to the insulin resistance emerging in mid to late gestation to ensure nutritional support for the developing fetus and maintain metabolic homeostasis in the pregnant mother (Newbern and Freemark, 2011).

Placental growth hormone (Than *et al.*, 2014.) is a single-chain peptide hormone, structurally related to pituitary growth hormone, hCG and prolactin. Up to the first 15 to 20 weeks of pregnancy, pituitary growth hormone is the main form of growth hormone present in the maternal circulation. From mid gestation until term, placental GH, synthesized by the syncytiotrophoblast, gradually replaces pituitary GH (Newbern and Freemark, 2011). Secretion of placental GH is regulated in part by placental size and maternal glucose. The primary function of GH is to ensure nutrient availability to the fetus by stimulating gluconeogenesis and lipolysis in the maternal compartment. Moreover, placental GH functions as an insulin antagonist and decreases maternal glucose utilization (Feldt-Rasmussen and Mathiesen, 2011).

The levels of adipocyte-derived signaling molecules such as leptin, resistin, adiponectin and pro-inflammatory cytokines have been reported to be associated to various pregnancy disorders and might affect the materno-fetal interface. Leptin appears to modulate female reproductive physiology at multiple levels including centrally via the hypothalamic-pituitary-gonadal axis, and by peripheral and local regulation. Leptin is mainly secreted by adipocytes, has important roles in regulation of body weight, appetite and energy homeostasis and its plasma levels are positively correlated to the amount of body fat. In pregnancy, leptin is also synthesized by the syncytiotrophoblast and released into both maternal and fetal circulations. Maternal circulating levels of leptin increase significantly in early pregnancy, reaching 30% higher levels at 12 weeks of gestation compared with pregravid women. Maternal leptin levels then peak in late second or early third trimester and decreases to pregravid concentrations immediately after delivery (Hauguel-De Mouzon *et al.*, 2006). Maternal body mass index is positively associated with leptin concentrations during pregnancy (Jansson *et al.*, 2008). It has been proposed that leptin released from the placenta may modulate maternal metabolism and partition

of nutrients to the fetus. The human placenta expresses leptin receptors, suggesting that leptin may regulate placental function. Indeed, leptin may act in a paracrine or endocrine manner to modulate angiogenesis and immunomodulation (Perez-Perez et al., 2013, Herrid et al., 2014), stimulate the secretion of hCG and IL-6 by human trophoblast cells in culture (Cameo et al., 2003), promote trophoblast invasion and activate placental nutrient transporters. Based on these observations, it has been speculated that high maternal leptin levels may be a link between maternal obesity and fetal overgrowth (Jansson et al., 2003).

Contrary to leptin, adiponectin promotes insulin sensitivity, has anti-inflammatory and anti-atherogenic properties and adiponectin levels are negatively correlated with body fat. In normal pregnancies, maternal serum adiponectin increases during first trimester and subsequently undergoes a modest decrease in maternal serum levels in the second and third trimester. Serum levels of maternal adiponectin are inversely correlated with birth weight and low maternal adiponectin is associated with increased risk of delivering large for gestational age infants by obese pregnant women or with gestational diabetes (Jansson et al., 2008). Adiponectin is secreted by maternal adipose tissue and modulates placentation by stimulating trophoblast migration and differentiation via specific receptors. Whereas adiponectin promotes insulin sensitivity in skeletal muscle and liver, recent findings show that adiponectin inhibits insulin signaling in the placenta, thereby reducing insulin-stimulated amino acid transport and subsequently decreasing fetal growth. Adiponectin does not cross the placenta and fetal adiponectin is positively associated to fetal adiposity and growth (Aye et al., 2013). In addition, adiponectin might promote trophoblast cells evasion of the maternal immune system by increasing the expression of cell surface molecules involved in the downregulation of maternal immune response to fetal antigens (D'ippolito et al., 2012).

Resistin is a signaling molecule induced during adipogenesis and is positively correlated with obesity. During pregnancy, maternal serum levels of resistin in early pregnancy are similar to those of non-pregnant women but increases significantly during the third trimester. Resistin is produced by the placenta, mainly by the syncytiotrophoblast. *In vitro* models using primary human cytotrophoblast cells and choriocarcinoma cell lines, demonstrated that resistin can modulate placental function by modifying the expression and activity of glucose transporters in placental cells. In low concentrations, resistin enhances glucose uptake and at high concentrations, it impairs this process (Di Simone et al., 2009). In addition, resistin has been linked to trophoblast invasiveness by upregulating the secretion and activity of metalloproteinases (Mu et al., 2006). Syncytiotrophoblast cells also synthesize other adipocyte-derived proteins such as visfatin, fibroblast growth factor (FGF21), placental protein 13 (PP13) and pregnancy-associated plasma protein A (PAPP-A) that may contribute to the establishment and maintenance of pregnancy (Than et al., 2014) (Campos et al., 2008) (Mesdaghi-Nia et al., 2016).

In conclusion, the placenta synthesizes and secretes numerous hormones and peptides that are critical for the regulation of the different stages of human pregnancy, ranging from, implantation to labor and also includes promoting maternal physiological adaptations to pregnancy and the initiation of breastfeeding. Deficient or altered production of these factors may alter placental development and function.

Transport

The human placenta is a highly specialized organ that transports nutrients from mother to fetus as well as removes waste products from the gestational compartment. Exchange between the mother and fetus relies on the highly differentiated barrier between the maternal and fetal circulations. Placental capacity for transport of nutrients increases with fetal demand as gestation progresses. Placental transport involves cellular mechanisms that participate in the delivery of macronutrients (glucose, amino acids and lipids), water, ions, vitamins, minerals and oxygen. All of these molecules reach fetal blood by traversing the placental barrier using a variety of mechanisms: simple diffusion, facilitated diffusion, active transport or endocytosis/vesicular transport. Vectorial transport across the placental barrier is established through the polarized distribution specific transporters in the syncytiotrophoblast microvillous membrane facing the maternal circulation and the basal membrane facing the fetal capillary. Details of the transport functions in the placenta are provided in the chapters *Placental transfer* and *Placental nutrient transport*.

Imprinted genes in the placenta

Most mammalian cells express their autosomal genes from two parental alleles. However, at some loci the allele inherited from one parent is suppressed which results in imprinted or monoallelic parent-of-origin specific expression. Imprinted genes exhibit expression differences in an allele-specific manner depending on parent of origin, usually resulting in the complete or partial silencing of one allele and very high expression of the other allele. Pregnancy involves a cooperative interaction between mother and fetus, and through a variety of maternal physiological adaptations the fetal demand for resources to support its growth are met. Resource allocation during pregnancy results in an inherent conflict between the mother and her fetus who carries the paternal allele. Although the mother benefits by the transmission of her genes to future generations, she has an interest in limiting the current fetus to retain resources for subsequent pregnancies. Limiting allocation of resources to the fetus is more relevant when the resources are limited (Fowden and Moore, 2012). The importance of conflict in nutrient allocation may vary between species and is proportional to the maternal weight that is utilized to support pregnancy. Maternal-fetal conflict results in differential expression of maternally and paternally inherited alleles in the fetus and placenta. Paternal inherited genes promote placental and fetal growth while maternally expressed genes have a limiting effect. Imprinted genes often impact resource allocation by the placenta. There are over one hundred confirmed imprinted genes in mice and approximately 50 of these maintain their imprinted status in humans and are expressed in embryonic, fetal and early postnatal stages of development. Recent research has supported the idea that genomic imprinting in the placenta may be an adaptive mechanism permitting plasticity of function in response to changing environmental conditions during

gestation (Wang et al., 2013). As imprinted genes regulate placental development and fetal growth, its implications in complicated pregnancies including low birth weight, intrauterine growth restriction, gestational diabetes and preeclampsia remain poorly understood (Cleaton et al., 2014) (Monk, 2015).

Fetal Unit

Fetal Membranes

Fetal membranes are extra-embryonic tissues, genetically identical to the fetus, which encircle the fetus and form a maternal-fetal interface. There are different morphological types of fetal membranes represented among the vertebrates. In humans, fetal membranes at term have an area of approximately 1000–1200 cm², where 30% overlay the placenta and the remaining 70% interact with the maternal tissues. The maintenance of the fetal membrane integrity is critical to the success of pregnancy where sufficient strength and elasticity of the tissues enables the tissue to double in size and support vigorous fetal movements, particularly toward the end of the pregnancy. Fetal membranes consist of several cell types including epithelial, mesenchymal and trophoblasts, which are embedded in an extracellular matrix that imparts tensile strength. Fetal membranes are multilayered tissues formed by two principal layers: the amnion and the chorion. The amnion is in direct contact with the fetus and is composed of five different layers: a single layer of epithelial cells, a basal membrane, the compact layer, the fibroblast layer and the intermediate or spongy layer. The chorion consists of a layer of connective tissue, a basal membrane and a region containing trophoblasts, which by term is firmly adhered to the maternal decidual tissue (Bryant-Greenwood, 1998). The decidua, a maternal tissue discussed below, is composed of differentiated stromal cells surrounded by an extracellular matrix that fuses with the chorion over the course of pregnancy. Collagens are the major structural components of the fetal membranes, where the major tensile strength is provided by the interstitial collagen type I and III, together with smaller amounts of types V, VI and VII. The structural integrity of fetal membranes is due to a precise balance of synthesis and degradation of collagens.

Fetal membranes undergo physical and biochemical changes during the process of normal labor, including increased the collagenolytic activity and apoptosis favoring the loss of structure, leading to the rupture of membranes necessary for the delivery of the fetus (Vadillo-Ortega and Estrada-Gutierrez, 2005). In addition, an inflammatory microenvironment is created within the fetal membranes during parturition, characterized by specific leukocyte subsets and the secretion of autocrine and paracrine mediators. Choriodecidual cells and infiltrated leukocytes secrete pro-inflammatory cytokines, prostaglandins and matrix metalloproteases during the onset of labor which may lead to spontaneous labor, the rupture of the membranes and eventually the delivery of the fetus (Gomez-Lopez et al., 2013, Cleaton et al., 2014).

Fetal membranes in humans are not vascularized which limits their function as an exchange surface for nutrients between mother and fetus. However, steroids and prostaglandins are secreted by the fetal membranes, allowing for paracrine signaling between the maternal and fetal compartments. Glucocorticoids are involved in fetal maturation and the initiation of labor (Myatt and Sun, 2010). In addition, fetal membranes can synthesize, store and secrete a wide variety of cytokines that can regulate and initiate local inflammatory responses believed to be involved in the physiology of normal parturition and in the pathology of premature delivery associated to intrauterine infection (Chavatte-Palmer and Tarrade, 2016). The maternal-fetal interface of the fetal membranes is a unique site that requires modulation of the local immune response to the allogenic fetus, while maintaining a defensive barrier against infectious agents. Several reports have evaluated human fetal membrane responses to entire bacteria and their products by using in vitro models to investigate intrauterine infection. Fetal membranes are capable of responding to bacterial products by secreting pro-inflammatory cytokines such as IL-1 β , TNF- α , and IL-6. Epithelial amnion cells react to infection by secreting IL-6 and IL-18. In vitro models suggest that in the presence of infection, the mechanisms leading to the rupture of the fetal membranes appear to be dependent on the nature of the infecting microorganism (Di Simone et al., 2009).

Maternal Unit

Decidua

The decidua is a transient layer that is localized between the fetal membranes and the myometrium and may play a role in the cross-talk between maternal and fetal compartments. It is formed during the secretory phase of the menstrual cycle as a result of elevated ovarian hormones such as estrogen and progesterone. The decidua is composed of glands, immune cells, blood and lymph vessels, and decidual stromal cells (DSCs) and fetal extravillous trophoblast (Mori et al., 2016). The interaction of the maternal leukocyte populations in the decidua with fetal trophoblasts is crucial at the time of placentation and for the success of pregnancy. Therefore, any disturbance in the decidualization process and/or maternal-fetal crosstalk could lead to pregnancy complications such as implantation failure and pregnancy loss (Sharma, S. et al., 2016).

There are three major process in which maternal-fetal cross-talk is essential for the maintenance of pregnancy: a) the establishment of immune tolerance, b) regulation of the trophoblast invasion, and c) remodeling of the spiral arteries (Romero et al., 2014). Defects in trophoblast invasion are associated with severe pregnancy complications affecting both mother and fetus. Cytokines and growth factors are key molecules involved in the regulation of trophoblast invasion and act either to stimulate such as IL-1 β , IL-6, IL-11, IL-8, RANTES, and IP-10 or inhibit; IL-10, IL-12 and vascular endothelial growth factor (VEGF) (Sharma et al., 2016).

Given their anatomical position, decidual cells are likely to be the first cells of the feto-maternal interface to be in contact and respond to pathogens and establish the immunotolerance mechanisms towards fetal antigens (Anders et al., 2017). There are

several critical windows in which the maternal immune system may be challenged with fetal alloantigens at the decidua: i) during implantation, ii) when extravillous trophoblast invade and remodel the maternal spiral arteries, iii) when the syncytiotrophoblast turnover sheds microvesicles, nanoparticles, microparticles and exosomes into maternal circulation. The female immune system undergoes constant transformation and adaptation beginning with each menstrual cycle and continuing through gestation with fertilization and implantation. Changes in the immune cell populations, secretory profiles and the immune effects of pregnancy-associated hormones in the decidua are some of the maternal adaptations allowing for immunotolerance (Hyde and Schust, 2016).

The establishment of the fetal-maternal unit is fundamental for the establishment and maintenance of pregnancy. This maternal-fetal interface serves two principal functions: (1) to act as an interface between the mother and fetus and allow nutrient and oxygen transfer and waste products removal, a function mainly orchestrated by the placenta; and (2) to protect the fetus from the extrauterine environment until it is fully developed, a function served by the fetal membranes and decidua. Although the structure and some functions of the fetal-maternal unit may vary between species, the endocrine and transport functions in the unit remain consistent. Abnormal establishment of the fetal-maternal unit may be involved in the pathogenesis of impaired implantation, recurrent miscarriages, intrauterine growth restriction and preeclampsia.

Fetal Endocrinology

Introduction to Fetal Endocrinology

The fetal hormone milieu is largely independent of maternal hormone because the placenta creates an impermeable barrier for most hormones, which provides distinct endocrine regulation in the maternal and fetal compartments. The initial information presented in this article describes general principles of endocrinology that all endocrinologists consider in adults. For example, hormone synthesis, secretion, transport, receptor binding, and clearance are important processes for endocrine systems and complications in any one of these processes will result in endocrine pathologies. In the fetus, the formation and maturation of the endocrine systems during development must be considered. Maturation of the endocrine system occurs after the formation of the gland because, even though synthesis of a hormone has begun, the endocrine tissues must also develop the responsiveness to secrete the hormone. Similar maturation processes also take place at target tissues, which need to express receptors and intracellular signaling proteins to receive and interpret the message conveyed by the hormone. Consideration of maturation during development involves an additional layer of complexity for understanding fetal endocrinology and also indicates a point for adaptive programming to various clinically important situations like placental insufficiency and intrauterine growth restriction.

Principles of Endocrinology

The classical definition of endocrinology states that hormones are chemical substances produced by specialized tissues and secreted into the blood, where they are carried to target organs to elicit a biological response. Investigations by physiologists, biochemists, and clinicians have shown that the classic definition, while appropriate for some endocrine systems, was restrictive because not all hormones are produced in specialized glands that are distinct from the target organ. These limitations have led to a broader definition: a hormone is a chemical substance that carries information between two or more cells. In this capacity, the endocrine system resembles the nervous system and is one of the two distinct mechanisms involved in communication within the body to maintain homeostasis by coordinating physiological interactions. These roles become apparent in several endocrine-related diseases such as diabetes and hypothyroidism.

Chemical Nature of Hormones

The chemical nature of hormones is highly variable, but in general hormones are classified into by four broad categories. These categories are lipids, proteins, peptides, and modified amino acids. Lipid hormones include steroids or vitamin D derived from cholesterol, and prostaglandins derived from arachidonic acid. Lipid hormones are usually hydrophobic or unable to dissolve in water. Protein and peptide hormones are synthesized in cells from amino acids and stored in granules until the cell is stimulated to release them into the extracellular space. Some protein hormones are glycosylated, which will further stabilize them after release, increasing their half-life by slowing their clearance compared to nonglycosylated proteins or peptides. Proteins and peptides are often hydrophilic allowing them to freely dissolve in water. Modified amino acids are produced biochemically in the cell from tyrosine or tryptophan. The solubility of these hormones in water is dependent on the modifications. Catecholamines and thyroid hormones are both derived from tyrosine. Catecholamine, epinephrine and norepinephrine, are hydrophilic and store in intracellular secretory vesicles, whereas thyroid hormones are hydrophilic.

Based on the chemical nature of hormones predictions can be made about their synthesis, storage, transport, and receptors. Hydrophilic hormones are more easily stored in intracellular compartments, and once released will interact with receptors on the plasma membrane. In contrast, hydrophobic hormones require protein chaperones to transport them through the blood and are free to diffuse across the plasma membrane to bind to intracellular receptors that act as ligand mediated transcription factors to initiate the cell response.

Biological Activity of Hormones

Autocrine, paracrine, and endocrine regulation of signaling describe the proximity between the endocrine cell and target tissue. Autocrine refers to a chemical-produced response in the same cell from which it was secreted. Paracrine describes a hormone that provokes a response in local, neighboring cell that is distinct from the cell secreting the hormone. Endocrine signaling is long-distance communication often using the blood for its distribution. Autocrine, paracrine, and endocrine communication allow for coordination of fetal development and preparation for postnatal life.

Hormones work in an induced fit, lock-and-key manner with the hormone being the ligand or in this scenario the key and the lock being a specific receptor opening the door of communication. There are intracellular receptors (nuclear) and cell membrane receptors (membrane-bound). Lipid-soluble hormones, like steroid hormones, diffuse directly across cell membranes and bind to intracellular receptors in the cytoplasm or nucleus. Receptor-hormone complex then bind to specific elements on the DNA to initiate transcription of RNA and increase translation of proteins. Water-soluble hormones, like amine, peptide, and protein hormones, utilize cell membrane receptors and second messenger signaling pathways because they cannot diffuse through the lipid

bilayer. A common second messenger used by hormones is cyclic adenosine monophosphate (cAMP). In this pathway, hormones bind to the membrane receptor (this is referred to as a G-protein coupled receptor), which cause a conformational change that activates a G-protein. The active G-protein then initiates adenylyl cyclase to catalyze the conversion of adenosine triphosphate to cAMP. This second messenger, cAMP, binds to the regulatory subunit of protein kinase A causing the release of active catalytic subunits to phosphorylate other intracellular proteins and elicit the biological response. Second messenger pathways allow for the amplification of the hormone signal leading to a faster, more efficient response. Whether intracellular or cell membrane-bound receptors are utilized, hormones are able to elicit specific and calculated responses to stimuli. These activities like the production of the hormone must mature during development.

Regulation of Hormone Secretion

Hormone concentrations are typically determined by rate of production, rate of delivery, and rate of degradation and elimination. Rate of production is controlled through feedback mechanisms, which allows the endocrine system to be finely tuned. Hormone secretion is predominantly regulated through feedback loops that can provide negative or positive feedback. Negative feedback is the most common method of homeostasis and results from either direct or indirect inhibition of hormone secretion. Positive feedback occurs when a hormone stimulates its release, reinforcing its secretion, which is rare and requires a terminal event. For example, delivery of the baby circumvents further secretion of oxytocin. Feedback loops allow for tight control of hormone secretion to maintain homeostasis within the system.

Neuroendocrinology: Hypothalamic–Pituitary Complex

The hypothalamus and pituitary are two separate organs that work together as the “command center” for many endocrine systems. Arising from ectoderm and neuroectoderm, the pituitary gland is present by 12 weeks of gestation, and the primary plexus of the pituitary portal blood vascular system begins development at 14 weeks being fully developed by 21 weeks in humans. The pituitary is located immediately beneath the hypothalamus, which contains measurable releasing hormones as early as 8 weeks of gestation. Four primary regions of the hypothalamus are the preoptic, supraoptic, tuberal, and mammillary (Porter, 1998). These regions are responsible for the regulation of blood pressure, energy metabolism, reproduction, body temperature, stress response, and circadian rhythm in the adult. Some hypothalamic hormones are synthesized and transported to the posterior pituitary gland, while others serve as releasing hormones that regulate secretion of anterior pituitary hormones. The hypothalamic–hypophyseal portal system connects a series of capillary beds that allows hypothalamic regulation of the anterior pituitary. Releasing hormones include: corticotrophin releasing hormone (CRH), thyrotrophin releasing hormone (TRH), gonadotrophin releasing hormone (GnRH), growth hormone releasing hormone (GHRH), and prolactin inhibitory hormone (dopamine). The hypothalamus also secretes somatostatin, which inhibits GH, and dopamine, which stimulates GH inhibits prolactin (PRL) secretion (Porter, 1998) (Table 1).

During development, the hypothalamus is vulnerable to genetic modulation and is influenced by maternal factors like undernutrition, obesity, and diabetes. The hypothalamus is known to regulate satiety as well as energy and peripheral glucose homeostasis in adults. Since the hypothalamus is sensitive to metabolic changes, negative environmental exposures, like elevated glucose, in utero can leave a lasting imprint on gene expression resulting in neurodevelopmental insufficiencies or increased risk of neurobehavioral issues (Omoy, 2011). Due to maternal over- or undernutrition, programming of hypothalamic genes like pro-opio-melanocortin and neuropeptide Y can lead to altered food consumption and glucose homeostasis. In growth restricted fetal baboons, it has been shown that appetitive neuropeptide balance is altered to promote increased appetite drive postnatally. Interestingly, the second half of pregnancy seems to be the critical window for programming of the hypothalamus in regards to food intake (Cun et al., 2013).

Pituitary Hormones: Adenohypophysis (Anterior)

The adenohypophysis consists of the anterior pituitary gland, also known as the pars distalis, and the much smaller pituitary stalk, pars tuberalis. The anterior pituitary secretes seven different hormones. The ability for the anterior pituitary to secrete so many different hormones is due to the various endocrine cell types that comprise the gland (Pocock et al., 2013). Somatotrophs make up the majority (50%) of the cell population and secrete GH. Its function is primarily anabolic, promoting protein synthesis and accretion both directly and indirectly. Thyrotrophs (5%) secrete thyroid-stimulating hormone (TSH), which promotes thyroid hormone secretion. Thyrotroph and somatotroph differentiation occurs by 10 weeks of gestation with lactotrophs differentiating last at 16 weeks. Lactotrophs (15–20%) secrete PRL by 16 weeks of gestation, which is known to play a significant role in lung maturation and peak in concentration in late gestation. Gonadotrophs (10%) secrete follicle-stimulating hormone (FSH) and luteinizing hormone (LH), which are synthesized by 9 weeks of gestation and reach their highest concentration mid-gestation. Corticotrophs (15–20%) primarily secrete adrenocorticotrophic hormone (ACTH) but can also secrete melanocyte-stimulating hormone (MSH). By 9 weeks of gestation, ACTH is detectable with the primary role being to stimulate adrenal glucocorticoid synthesis and regulate metabolism and stress response (Pocock et al., 2013). The hypothalamus controls secretion of FSH, LH, ACTH, MSH, and TSH through releasing hormones (Kota et al., 2013). PRL is primarily regulated through the inhibitory effect of dopamine. The hypothalamus also controls GH through both GHRH and somatostatin, which is also known as growth hormone-inhibiting hormone.

Table 1 Summary of the development of endocrine systems

<i>Hormone</i>	<i>Formation</i>	<i>Endocrine gland</i>
Coricotrophin releasing hormone (CRH)	9 weeks	Hypothalamus
Thyrotrophin releasing hormone (TRH)	8 weeks	Hypothalamus
Gonadotrophin releasing hormone (GnRH)	9 weeks	Hypothalamus
Prolactin inhibitory hormone (dopamine)	10 weeks	Hypothalamus
Somatostatin (GHRH)	10 weeks	Hypothalamus
Growth hormone (GH)	10 weeks	Anterior pituitary
Thyroid-stimulating hormone (TSH)	10 weeks	Anterior pituitary
Prolactin	16 weeks	Anterior pituitary
Follicle-stimulating hormone (FSH)	9 weeks	Anterior pituitary
Luteinizing hormone (LH)	9 weeks	Anterior pituitary
Adrenocorticotrophic hormone (ACTH)	9 weeks	Anterior pituitary
Melanocyte-stimulating hormone (MSH)	9 weeks	Anterior pituitary
Arginine vasopressin (AVP)	10 weeks	Posterior pituitary
Oxytocin	11 weeks	Posterior pituitary
Dehydroepiandrosterone sulfate (DHEA-S)	9 weeks	Adrenal cortex
Glucocorticoids (Cortisol)	12 weeks	Adrenal cortex
Catecholamines (norepinephrine)	7 weeks	Adrenal medulla
Testosterone	8 weeks	Gonads (male)
Estrogen	10 weeks	Gonads (female)
Thyroxine (T ₄)	12 weeks	Thyroid gland
Parathyroid hormone (PTH)	10 weeks	Parathyroid glands
Insulin	10 weeks	Pancreas
Glucagon	10 weeks	Pancreas
Somatostatin	10 weeks	Pancreas
Pancreatic polypeptide	10 weeks	Pancreas
Insulin-like growth factors (IGF)	9 weeks	Liver

Throughout gestation, fetal GH concentrations fluctuate with the highest concentrations being at mid-gestation due to the formation of the somatotrophs and subsequent maturation of the pituitary feedback control systems to regulate GH secretion in the third trimester. In contrast to GH, PRL concentration will remain low until after 25 weeks of gestation peak at term, showing autonomous secretion of PRL is limited early in lactotrophs (Kota et al., 2013). Postnatally, GH acts through receptors in the liver and other tissues to stimulate insulin-like growth factor 1 (IGF-1) and IGF-2, albeit to a lesser degree. In the fetus, the GH receptors in the liver are low suggesting they are less responsive to GH from the fetal pituitary. Additionally, high placental lactogen concentrations in the fetus may saturate GH receptors even though the affinity of placental lactogen is lower than GH for the GH receptors (Gluckman and Pinal, 2002). One additional piece of evidence suggesting that the action of pituitary GH in the fetus is not effective at regulating fetal growth is that the growth of an anencephalic fetus is nearly normal. Similarly, PRL receptors are present in several fetal tissues and may be important for adipogenesis, but crosstalk from placental lactogen is also expected with PRL receptors.

Pituitary Hormones: Neurohypophysis (Posterior)

The neurohypophysis consists of hypothalamic neurons that extend through the median eminence and terminate the posterior pituitary. The magnicellular neurons of the supraoptic and paraventricular nuclei secrete oxytocin and arginine vasopressin (AVP). Oxytocin synthesis begins by 11 weeks and increases just prior to parturition. Oxytocin is known for its role in parturition and lactation as well as social behaviors; however, its role in fetal development is less understood. AVP production begins by 10 weeks of gestation (Kota et al., 2013). AVP, or antidiuretic hormone, regulates blood volume and osmolality via renal tubule water reabsorption (V₂ receptors) and vasoconstriction (V_{1a} receptors) in adults. In fetal sheep, responsiveness to volume and osmolar stimuli is well developed in late gestation. AVP concentrations increase in response to hypoxia in the sheep fetus, which suggest that AVP functions as a fetal stress-responsive hormone. The vasopressor actions of AVP may be critical activities during fetal hypoxia or hemorrhage. Not surprisingly, AVP has little effect placental blood flow because restriction of oxygen and nutrient transfer from the mother to the fetus caused by restricted flow is expected to lead to greater hypoxic stress.

The hypothalamic–pituitary complex has specific target organs including adrenal glands, gonads, and thyroid gland, coordinating important events in fetal development. These specific endocrine axes are discussed below.

Hypothalamic–Pituitary–Adrenal Axis

The hypothalamic–pituitary–adrenal axis controls stress response by intertwining the central nervous system and endocrine system. Adrenal glands, which sit above the kidney, begin developing by week 4 of gestation. Fetal adrenal glands have a cortex, which is

able to produce three types of steroid hormones: androgens (fetal zone), glucocorticoids (transitional zone), and mineralocorticoids (definitive zone). The cortex is steroidogenically active by 9–12 weeks, producing primarily the androgen dehydroepiandrosterone sulfate (DHEA-S). The relatively high and sustained production of DHEA-S from adrenal glands and conversion to 16 α -hydroxy-DHEA-S in the fetal liver forms the maternal–fetal–placental unit (Kota et al., 2013). Thereby, adrenal glands provide substrates for estradiol and estrone production in the placenta to overcome the lack of 17 α -hydroxylase/17,20-lyase expression in the trophoblast cells. Placental human chorionic gonadotrophin plays a role in early growth but maintenance and growth after 15 weeks becomes dependent on ACTH, demonstrating maturation of the axis (Ng, 2000). The fetal adrenal function is largely geared to produce inactive steroidogenic products.

The majority of fetal glucocorticoids (cortisol) in circulation are secreted from the adrenal glands with the rest coming from placental transfer. Metabolic clearance rates of cortisol to cortisone are rapid and raise the inactive cortisone concentrations in fetal circulation. This inactivation process may be critical to protect the fetus from catabolic effects of cortisol. The fetal hypothalamic–pituitary–adrenal axis progressively matures after mid gestation and CRH–ACTH stimulation of glucocorticoid secretion develops its negative feedback regulation (Ng, 2000). Glucocorticoid receptors are members of the nuclear receptor family, and are present in most fetal tissues after mid-gestation and play important roles in fetal development. In late gestation, there is a cortisol surge, which is crucial to mature fetal organs and prepares the fetus for delivery. In addition to cortisol production by adrenal glands, tissue-specific expression of 11-ketosteroid reductase increases in fetal lung and liver, which promotes the conversion of cortisone to cortisol locally to induce maturation.

Although glucocorticoids are necessary for normal brain development, inappropriate exposure to excess glucocorticoids can have a lasting impact postnatally. The hypothalamic–pituitary–adrenal axis is susceptible to permanent adaptation from prenatal stressors, which is associated with increased maternal stress (Fowden and Forhead, 2004). Fetal adaptations to maternal stress are dependent on both timing of insult during gestation and duration of the insult. In guinea pigs, maternal stress on days 50–52 of gestation proved to be a critical developmental window because these offspring have elevated basal adrenocortical activity compared to offspring stressed at later ages that displayed normal function. A similar study in nonhuman primates generated the same manifestation of elevated basal adrenocortical activity, but no critical window of programming was evident. Some rodent and porcine studies suggest that hypothalamic–pituitary–adrenal axis programming is sex-specific, with females being more vulnerable to adaptations. Although many studies have been done in various species, little research has been done in humans. In children of mothers that presented with stress and anxiety, salivary cortisol concentrations were elevated at 5 years of age. This is similar to female piglets that were exposed to maternal social stress in utero exhibiting elevated salivary cortisol in response to social stress (Kapoor et al., 2006). Mechanisms of maternal stress have been proposed such as placental CRH stimulation of fetal hypothalamic–pituitary–adrenal axis and maternal elevation in catecholamines leading to abnormal uterine blood flow, which stimulates the fetal hypothalamic–pituitary–adrenal axis. Chronic activation of the hypothalamic–pituitary–adrenal axis postnatally can lead to long-term consequences like psychological dysfunction, as well as metabolic and cardiovascular disease.

Hypothalamic–Pituitary–Gonadal Axis

The hypothalamic–pituitary–gonadal axis controls sexual development and reproduction. Gonadotrophs in the anterior pituitary secrete FSH and LH in response to GnRH. Due to inhibitory action of testosterone in male fetuses, circulating LH and FSH concentrations are generally low with the peak concentrations occur between 14 and 21 weeks of gestation. In female fetuses, LH and FSH concentrations are higher than males. The ratio of FSH/LH is also higher in females compared to males in utero. FSH and LH concentrations decline late in gestation due to the development of neuroendocrine responsiveness to negative gonadal feedback. Near term, pituitary hormones are needed for granulosa cell and follicular proliferation. The ovary also produces inhibin in utero though significantly less than males, which could also explain higher gonadotropin levels. Fetal sexual differentiation does not depend on gonadotropins from the pituitary but on the presence of the *SRY* (sex-determining region on the Y) gene and anti-Müllerian hormone. The hypothalamic–pituitary–gonadal axis continues to be fine-tuned during the neonatal period and throughout postnatal development, with most of the reproductive maturation occurring during puberty.

It is known that adverse in utero exposure to testosterone can produce reproductive (infertility) and metabolic deficiencies (obesity and insulin resistance) into adulthood. This has been reproduced in rats, nonhuman primates, and sheep. Exposure to testosterone between 30 and 60 days of gestation in fetal sheep resulted in growth restriction and consequent reductions in birth weight. Females also exhibited catch-up growth postnatally while males did not. Early pregnancy appears to be the critical window for fetal programming, which is concerning due to fetal exposure possibilities like continued contraceptive steroid use, unintentional environmental exposure, use of anabolic steroids, or from maternal diseases like polycystic ovarian syndrome, which increase circulating androgens (Manikkam et al., 2004). This knowledge allows growth restriction and catch-up growth to be a potential indicator for adult disease.

Hypothalamic–Pituitary–Thyroid Axis

The thyroid gland forms around week seven of gestation making it one of the first endocrine glands. It originates from the primitive pharynx, which forms the majority of the gland (median thyroid), as well as the neural crest, which gives rise to the rudimentary lateral thyroid. The thyroid gland undergoes three histologically distinct stages of growth and differentiation: precolloid (7–10 weeks), colloid (10–11 weeks), and follicular (11 weeks). By week 12, the thyroid is functional and is critical for neural development and metabolism stimulation. The thyroid is fully functional by 16–18 weeks of gestation and continues to expand throughout gestation. Prior to fetal thyroid development, the fetus is dependent on maternal thyroid hormone for brain

development. The thyroid gland synthesizes thyroxine (T_4), which is a prohormone because triiodothyronine (T_3) is normally produced at the target tissues by 5'-monodeiodinase. TSH secretion begins by 10 weeks of gestation and reaches adult concentrations between 26 and 36 weeks. In early development, TSH likely serves to regulate T_4 secretion through negative feedback by T_4 versus TRH stimulation. At the thyroid gland, TSH promotes follicular growth as well as thyroid hormone synthesis and secretion. When T_3 and T_4 concentrations are too low, TSH production is increased. Once appropriate concentrations are reached, TSH production is decreased. Late in gestation, T_4 and T_3 concentrations are increased resulting in low TSH; however, after birth, TSH, T_4 , and T_3 concentrations increase dramatically. Though active during late fetal development, the hypothalamic–pituitary–thyroid axis will not fully mature until postnatal life (Forhead and Fowden, 2014).

The impact of thyroid hormones in human fetal development is not fully understood. Although in fetal sheep growth and bone maturation are affected by hypothyroidism, human fetal development does not appear to be drastically impacted, possibly due to sufficient maternal thyroid delivery across the placenta. In the fetal sheep, hypothyroidism results in asymmetric growth restriction with muscle mass reduction as a primary consequence, along with other secondary development abnormalities. In particular hypothyroidism in fetal sheep shows deficiencies in maturation of the lung and cardiovascular systems. Fetal thyroid hormones are able to modulate accretion and differentiation of tissue as well as metabolic processes, promoting fetal development (Fowden and Forhead, 2004).

Parathyroid Glands and Calcium Homeostasis

Parathyroid glands arise from the third and fourth pharyngeal pouches (inferior and superior). In humans, parathyroid hormone (PTH) secretion begins by 10 weeks of gestation. PTH is produced from chief cells, and it controls plasma calcium concentration and counters calcitonin from the parafollicular cells in the thyroid gland. In the fetus, both endocrine systems are functional during the second and third trimesters. Receptors for PTH can be found in bone, the kidneys, and the gastrointestinal tract. There are five main physiological impacts of PTH: increased gastrointestinal calcium absorption, stimulation of osteoclasts to free calcium and phosphate from bone, increased calcium reabsorption but decreased phosphate reabsorption by the kidneys, and stimulates calcitriol (vitamin D) production in the kidneys. In sheep fetal calcium concentrations are greater than the mother, which indicates there is active placental transport from maternal circulation. The parathyroid hormone-related protein (PTHrP) is a regulatory protein expressed during organogenesis (Manley, 2015). Studies in various mouse models and humans suggest that PTH and PTHrP are required for fetal bone development and critical for regulation of serum minerals. PTHrP, and possibly PTH, is necessary to stimulate the placental transfer of calcium and magnesium. Loss of either hormone is known to result in hypocalcemia with the most significant hypocalcemia occurring with the loss of both PTH and PTHrP (Kovacs, 2014).

Endocrine Pancreas and Glucose Homeostasis

Mature pancreatic islets consist of insulin-secreting β -cells, glucagon-secreting α -cells, somatostatin-secreting δ -cells, and pancreatic polypeptide-secreting F-cells. β -cell proliferation starts 8 weeks into gestation in humans and continues throughout gestation with primitive islets forming around 11 weeks of gestation. Since insulin does not cross the placenta, fetal β -cells synthesize and secrete insulin and become responsive to glucose and other secretagogues around mid-gestation (Pictet et al., 1972). In sheep, β -cell responsiveness to glucose and arginine increases significantly after mid-gestation, showing β -cell maturation parallels the maturation of insulin action. In the fetus, insulin is a potent growth-promoting hormone, and umbilical cord plasma insulin concentrations are positively correlated to birth weight as well as glucose concentrations. Glucagon counteracts insulin action and promotes gluconeogenesis in the liver. In the sheep fetus, maternal starvation or administration of exogenous glucagon will stimulate hepatic glucose production. However, this appears to require an upregulation of enzymes in hepatocytes because normally fetal gluconeogenesis is minimal. Fetal development of the pancreas is critical for appropriate glucose homeostasis, while disrupted development can lead to metabolic disease as an adult.

Fetal Growth Regulation by Insulin-like Growth Factors

The fetal liver and placenta produce IGFs to stimulate fetal growth. IGF-1 and IGF-2 promote cell division, differentiation, and migration with IGF-2 being dominant in embryonic growth and IGF-1 becoming dominant later in gestation and postnatally. Mice that lack IGF-2 and IGF-1 receptors have significant growth restriction compared to mice with mutations of the IGF-1 gene and IGF-1 receptors. In mice models with specific liver IGF-1 deletion, IGF-1 concentrations were significantly reduced and peripheral insulin action was impaired. In late gestation, IGF-1 concentrations correlate directly to birth and placental weights. Fetal IGF-1 production is influenced by glucose and insulin concentrations, while IGF-2 is only governed by glucose. Placental IGF-2 is detected at 6 weeks of gestation and is thought to regulate placental growth, through nutrient availability, and aid in maintenance of pregnancy. The placenta is also able to secrete IGF-1 into fetal circulation. Unlike postnatal growth, fetal IGF-1 concentrations are not dependent on pituitary GH, owing to the high placental lactogen concentrations. Decreased IGF-1, insulin and T_4 are associated with a decline in fetal nutrient availability and growth restriction. Alternately, overexpression of the IGF-2 gene is known to cause overgrowth in mice models (Fowden and Forhead, 2004). Therefore, IGFs play an important role in nutrient and substrate availability to the growing fetus.

Intrauterine Growth Restriction

Intrauterine growth restriction (IUGR) affects up to 10% of all pregnancies and is often caused by placental insufficiency. Placental insufficiency is the failure of the placenta to deliver adequate oxygen and nutrients to maintain fetal growth rates, which causes the fetus to become hypoxemic and hypoglycemic. In order to resolve the conditions of placental insufficiency, the fetus diverts its nutrients to critical tissues causing adaptations in the body's structure, function, and metabolism. Observational data in humans indicates that developmental adaptations in both insulin secretion and insulin sensitivity to IUGR result in lifelong complications that increase the risk of developing glucose intolerance, diabetes, and cardiovascular disease.

Chronic low glucose and oxygen concentrations associate with placental insufficiency-induced IUGR lower plasma insulin concentrations, reduce β -cell mass, and impair β -cell function (Limesand and Rozance, 2017). In sheep fetuses with placental insufficiency and IUGR, body-weight specific glucose utilization rates, measured with tracer methodologies, are normal even though plasma insulin concentrations are substantially less than age-match control fetuses. This leads to the conclusion that IUGR fetuses have greater insulin sensitivity. However, these same IUGR fetuses have lower rates of umbilical (fetal) glucose uptake, which requires the IUGR fetuses to make a substantial portion of the glucose to maintain their glucose utilization rates. This suggests that the IUGR fetus develops a specific endocrine profile that promotes gluconeogenesis but also produces adaptive changes in skeletal muscle to enhance nonoxidative glucose uptake. Furthermore, the portion of noninsulin sensitive tissues, for example neuronal tissues, may also partially explain the near normal glucose utilization rates because IUGR fetuses tend to grow asymmetrically and have greater brain to liver ratios. These alterations in metabolism and asymmetric growth are influenced by endocrine actions.

Fetal responses to hypoxemia and hypoglycemia elevate norepinephrine and epinephrine. High catecholamines have been shown to slow fetal growth independent of other IUGR conditions and promote asymmetric growth (Limesand and Rozance, 2017). In fetal sheep, the sustained high catecholamine concentrations account for approximately 50% of the growth restriction. Catecholamines act via the adrenergic receptors (AR), which are G-protein coupled receptors. Adrenergic stimulation is tissue-specific due to the localized expression of the nine different isoforms of the AR. Catecholamines regulate blood glucose concentrations and under stressful conditions stimulate glycogenolysis and gluconeogenesis in the liver, but also act on the skeletal muscle to increase lactate release to provide gluconeogenic substrates to the liver. Sustained exposure to β 2-AR agonists increase nonoxidative glucose uptake, which indicates that in the IUGR fetus with chronically high concentrations of catecholamines cause the increased uptake but decrease oxidative metabolism of glucose in skeletal muscle. This will support higher lactate release with the appearance of greater insulin sensitivity for glucose utilization. Catecholamines also inhibit insulin secretion (α ₂-AR), thereby lowering plasma insulin concentration to allow hepatic glucose production, preferentially channeling glucose to the brain. The interplay between catecholamines and insulin are proposed to support the Cori cycle, also known as the Lactic acid cycle in IUGR fetuses (Fig. 1).

Fig. 1 Schematic for endocrine regulation for glucose production in the IUGR fetus. The Cori cycle is proposed in IUGR fetuses because the increase in norepinephrine, the primary fetal catecholamine, stimulates lactate release and inhibits oxidative phosphorylation in skeletal muscle. Catecholamines also inhibit insulin secretion to decrease oxidative metabolism in skeletal muscle, but the muscle counteracts the low insulin concentrations by increasing glucose uptake appearing to be more insulin sensitive. The low insulin concentrations limits its ability to suppress hepatic gluconeogenesis, which is enhanced by high catecholamines.

Epidemiological studies show that fetal adaptations to IUGR lead to β -cell dysfunction after parturition and increase the odds of developing coronary heart disease, type 2 diabetes, stroke, and hypertension with advanced age. In various animal models of IUGR (guinea-pig, rat, sheep), the postnatal offspring experienced obesity, insulin resistance, glucose intolerance and/or hypertension (Fowden and Forhead, 2004). These parallels allow for IUGR to be studied across a range of animal models working toward an effective treatment.

Summary

Fetal endocrinology plays a significant role in preparing the fetus for postnatal life and regulates several aspects of development and growth. The concept that physiological processes can be modulated during critical windows of development is a theme seen throughout the article. It is important to elucidate if these adaptations have lasting impact on the fetus in postnatal life. Because this review focused primarily on the role hormones in fetal growth, development, and metabolic homeostasis, other aspects of fetal endocrinology may not have been addressed.

Protein Hormones

Human Chorionic Gonadotrophin (hCG)

Structure and synthesis

hCG is a glycosylated protein composed of α and β subunits and exhibits a molecular weight of 37,180. hCG- α is comprised of 92 amino acids and is located on chromosome 6q14-q21. hCG- β is comprised of 145 amino acids and is structurally similar to the β -subunit of pituitary luteinizing hormone (LH), differing only in the terminal 28 amino acids. The β -subunit of hCG is encoded by a cluster of nonallelic genes (BhCG 1–8) located on chromosome 19q13.32. There are five variants of hCG, including hyperglycosylated hCG (hCG-H) synthesized by extravillous cytotrophoblasts (EVT) and sulphated hCG produced by the pituitary. hCG is produced by the placental villous cytotrophoblasts prior to week 6 of human pregnancy and by the syncytiotrophoblast thereafter. hCG is detectable in maternal blood 1–3 days after implantation, exhibits peak levels at 8–12 weeks of gestation, then declines and remains relatively constant thereafter (Fig. 1). Maternal serum hCG levels are predictive of onset of pregnancy and complications of pregnancy. For example, hCG levels are increased in women who develop hypertension, preeclampsia and carry a Down syndrome fetus, reduced in pregnancies complicated by fetal growth restriction (FGR), and may also serve as a predictor of pregnancy outcome, e.g., preterm birth and fetal demise.

cAMP, which stimulates protein kinase A (PKA) and phosphorylation of CREB(s) essential for binding to cAMP response elements (CRE), increases hCG α and β . The human placenta produces a gonadotrophin-releasing hormone (GnRH) which stimulates hCG production. Numerous other factors, including growth factors and steroid hormones, may also modulate hCG expression by trophoblast cells, although our understanding of the physiological role of these other factors is incomplete.

Function

The most well established action of hCG is regulation of the maintenance and function of the corpus luteum in early pregnancy. hCG binds to the LH/CG receptor to maintain the life span of, promote angiogenesis within, and stimulate progesterone and

Fig. 1 Serum concentrations of human chorionic gonadotropin (hCG), human placental lactogen (hPL), prolactin (PRL), cortisol, progesterone (Prog), estrone (E₁); estradiol (E₂) and estriol (E₃) during pregnancy From Rebar, R. W. (1999). The breast and the physiology of lactation. In: Creasy, R.W., Resnik, R. (eds.). Maternal-fetal medicine. 4th edn., pp. 106–121. Philadelphia, PA: WB Saunders Co.

estradiol synthesis by the corpus luteum. hCG stimulates luteal progesterone and estradiol production by increasing low-density lipoprotein (LDL) receptor-mediated uptake of cholesterol substrate and increasing the expression of key enzymes, including P-450 cholesterol side-chain cleavage (P-450_{scc}), 3 β -hydroxysteroid dehydrogenase (3 β -HSD) and aromatase (P-450_{arom}), required for steroidogenesis. hCG also develops and stimulates testosterone production by the fetal testes in the first trimester, a process essential for differentiation of the internal duct system and external genitalia in the male fetus. hCG also stimulates relaxin production by the corpus luteum, which may prevent regression of luteal cells and elicit vascular effects in other organs.

Recent studies indicate that hCG has more widely different functions. Thus, hCG produced by the blastocyst promotes decidualization and endometrial receptivity for implantation and interleukin-1 (IL-1) signaling in endometrial stromal cells leading to increased angiogenesis, thereby coordinating embryonic signaling with endometrial function to enhance embryonic growth. hCG also appears to promote immune tolerance by attracting T regulatory cells to the maternal-fetal interface and binds to its receptor expressed on villous cytotrophoblast to enhance fusion of these cells and thus syncytiotrophoblast formation and placental development. hCG reduces oxytocin-stimulated uterine myometrial smooth muscle contraction by activating large conductance calcium-activated potassium channels and decreasing intracellular levels of cyclic nucleotides that regulate contractility. Whether the decline in hCG levels late in gestation facilitates oxytocin-induced myometrial contractions remains to be determined.

hCG action involves activation of the hCG receptor and induction of cAMP and protein kinase A (PKA). cAMP-induced PKA signaling involves binding of the regulatory subunits of PKA to A-kinase anchoring proteins (AKAPs) expressed in the placenta. Such binding ensures subcellular compartmentalization of PKA and thus spatial and temporal regulation of PKA signaling events. The spatiotemporal regulation of PKA signaling by hCG appears to underpin its action on placental function. Finally, although hCG and LH act on the same receptor, intracellular signaling may be quantitatively and/or qualitatively different, e.g., hCG a more potent stimulator of cAMP production.

Placental Lactogen (PL)

Structure and expression

PL, also designated chorionic somatomammotropin (CS), is a member of the growth hormone (GH) family which also consists of pituitary GH (GH-N) and placental GH variant (GH-V). Human PL (hPL) is a single-chain polypeptide with 191 amino acids and a molecular weight of 22,279. PL, GH and prolactin exhibit structural homology. Three genes, CSH-1, CSH-2 and CS-L, encode PL and exhibit 94–98% sequence homology in their coding and flanking regions. Members of the CCAAT/enhancer-binding protein (C/EBP) and ETs family of transcription factors differentially modulate CSH1 and CSH-2 by regulating promoter/enhancer complexes and/or chromatin modification and thus may contribute to expression of CS in the placenta and lack of expression in the pituitary.

PL is synthesized by placental villous trophoblasts and differentiation of cytotrophoblasts into the syncytiotrophoblast during the first trimester of human pregnancy result in an exponential upregulation of PL production (**Fig. 1**). Maternal serum PL levels correlate directly with placental mass and approximate 5–10 μ g/mL near term. Because PL appears to have a role in modulating intermediary metabolism within the mother the effects of components of intermediary metabolism on PL synthesis have been investigated. Prolonged fasting increases and hyperglycemia decreases the secretion of PL, while short-term alterations in glucose have little impact. Moreover, high density lipoprotein (HDL) stimulates PL secretion by human trophoblast cultures. Growth factors, GH-releasing hormone (GHRH), steroids, and neurotransmitters either stimulated, inhibited, or had no effect on PL release in vitro. Thus, a clear understanding of the physiological regulation of PL secretion has not been established, possibly resulting from the different experimental approaches employed.

Function

Since PL, GH and prolactin share similar structure, and PL binds with high affinity to prolactin and GH receptors, it is not surprising that PL has effects on intermediary metabolism, growth, and lactogen function. Thus, PL stimulates pancreatic islet beta cell proliferation and insulin secretion and is necessary for pancreatic beta cell development. PL activates the Akt and MAPK signaling pathway, phosphorylation of JAKs/STATs, and expression of homeobox transcription factors. It has been suggested that lactogenic hormones maintain beta cell mass and function under conditions of stress and nutrient deprivation to protect against the development of gestational diabetes ([Arumugam et al., 2008](#)). During fasting PL reduced insulin sensitivity and induced glucose intolerance at mid to late pregnancy. The latter effects along with an increase in lipolysis may promote utilization of free fatty acids as a source of energy for the mother, while sparing glucose as a primary source of energy for the fetus. PL also may have a role in promoting fetal growth, since PL stimulated amino acid uptake by human fetal fibroblasts and skeletal muscle, effects mediated by IGF-I. PL also stimulated human mammary gland epithelial cells and ductal growth and lactogenesis.

GH-V is a glycosylated protein which differs from GH-N by 15 amino acids. GH-V is synthesized by the syncytiotrophoblast and maternal circulating levels progressively increase with advancing pregnancy. GH-V binds to the prolactin and GH receptors and exhibits somatotrophic and metabolic effects and may also modulate insulin action during pregnancy. PL and GH-V appear to be differentially expressed in association with altered fetal growth, possibly as consequence of polymorphisms in the locus control region and binding of regulatory transcription factors to the promoter. Thus fetal growth restriction (FGR) is associated with lower placental PL and GH, but not GH-V expression, while PL levels are greater in pregnancies with large for gestational age babies. It has been suggested that the divergent regulation of PL and GH-V may provide adaptive maternal and fetal benefits, in which changes in PL and GH-V induced by placental insufficiency alter the production of insulin and/or IGF-1, leading to decreased or increased fetal

growth (Newbern and Freemark, 2011). Thus, PL may act in concert with prolactin, GH-N, and other growth factors (e.g., IGFs) in regulating metabolic adjustments and fetal growth during human pregnancy.

Placental Growth Factors

The human placenta synthesizes numerous growth factors the most physiologically relevant of which are insulin-like growth factor (IGF)-I and -II, transforming growth factor β (TGF β), epidermal growth factor (EGF), vascular endothelial growth factor (VEGF), and endocrine gland (EG)-VEGF.

IGF-I and -II

IGF-I and IGF-II are structurally similar to insulin, approximate 7600 kDa and are comprised of α and β chains. The IGF-I gene is located on chromosome 12q22–24.1 and transcription is governed by two promoters. The IGF-II gene is located adjacent to the H19 gene on chromosome 11p15.5 and both genes are imprinted. Imprinted genes that are paternally expressed, such as IGF-II, promote fetal growth, whereas those maternally expressed, e.g., H19, are growth suppressors. Loss of imprinting of the IGF-II gene is extensive in placentas of pregnancies with FGR. Circulating IGF-I and -II are bound to binding proteins (IGFBP-1-6) that control the availability, stability and activity of the IGFs. IGFBP-3 binds 70%–80% of total maternal serum IGF-I and IGF-II. The physiologic actions of IGFs are controlled by IGF-I and IGF-II receptors. The IGF-I receptor binds IGF-I > IGF-II > insulin and the IGF-II receptor binds IGF-II > IGF-I but not insulin. IGF receptor signaling involves receptor autophosphorylation and activation of PI3K, ERK/MAPK and/or Akt.

IGF-I is expressed primarily in the placental syncytiotrophoblast, while IGF-II is expressed in placental cytotrophoblasts, syncytiotrophoblast, extravillous trophoblasts (EVT) and fibroblasts. Placental expression and maternal serum levels of IGF-I and IGF-II increase with advancing human pregnancy. Although the regulation of placental IGF expression is incompletely understood, placental expression and serum levels of GH-V and IGF-I are positively correlated, suggesting that GH-V is a primary regulator of placental IGF-I and supporting a role for GH-V in promoting fetal growth via regulation of IGF-I.

IGF-I and IGF-II appear to have important roles in promoting placental and fetal growth (Murphy et al., 2006; Sferruzzi-Perri et al., 2017). Thus, mice with deletions of IGF-I and/or IGF-II have small pups and IGF-I-deleted mice die before reaching adulthood. Although placental growth is normal in IGF-I knockouts, placentas are small and hypoplastic in IGF-II-null animals. Administration of IGF-I to growth-restricted fetal sheep and guinea pigs restored growth (Sferruzzi-Perri et al., 2013) via up-regulating placental nutrient transporters. Moreover, severe FGR occurs in human infants with a mutation of the IGF-I receptor. Collectively, it appears that IGF-I has a role in fetal growth and development, while IGF-II is more important for placental development. Along with their anabolic effects, the IGFs may promote fetal-placental growth by proliferation of the placental syncytia and uterine artery remodeling to promote maternal-fetal exchange. Importantly, IGF-I and II do not act alone and a complex regulatory interrelationship between the IGFs and insulin, thyroid hormone, cortisol, leptin, and nutritional drivers, appear to control placental and fetal growth (Fig. 2).

TGF β

TGF β s are members of a superfamily of cytokines that includes activins, inhibins, and bone-morphogenic proteins. Three TGF β isoforms, TGF β -1, -2 and -3, are encoded by three different genes. TGF β -1 is expressed primarily in the villous placenta, TGF β -2 in the decidua and TGF β -3 in villous and extravillous trophoblasts. TGF β members bind to the type I and II receptors, thereby activating serine/threonine kinase activity. The TGF β family may play a role in fetal growth, directly or indirectly via regulating placental function. TGF β -1 and -3, as mediated by connective tissue growth factor (Cheng et al., 2017) and the TGF β -binding proteoglycan decorin, act in a paracrine manner to suppress EVT invasion. TGF β -1 and -3 expression is increased with preeclampsia and exacerbates placental dysfunction and the associated complications of adverse pregnancy.

Activin is composed of subunits β_A and β_B that dimerize to form activin A, B and AB. Inhibin is comprised of α and β subunits forming inhibin A and B. Activin A and inhibin A are expressed in the syncytiotrophoblast, cytotrophoblast and decidua and maternal serum levels increase with advancing gestation. Activin A and inhibin B act in a para/autocrine manner to regulate cell proliferation and differentiation, and roles for placental development, vascular adaptation of pregnancy and onset of labor have been proposed. Activin A and B may modulate inflammatory processes and immunity during pregnancy by regulating production of interleukin, neutrophils, monocytes, and lymphocytes. Activin A levels are elevated and may participate in intra-amniotic infection and preterm birth.

EGF

EGF is a member of the EGF superfamily comprised of heparin-binding EGF-like growth factor (HB-EGF), amphiregulin, betacellulin, epiregulin, epigen, neuregulins 1–6 and TGF α . Each EGF member activates four receptors termed HER-1-4. Receptor activation is complex and controlled by spatiotemporal expression, post-translational processing and ectodomain shedding of the ligands. EGF receptors are expressed in cytotrophoblasts, syncytiotrophoblast and decidua. Maternal serum EGF levels are highest in the first trimester. EGF plays a role in placental development since EGF-null mice are growth-retarded, HER-null mice die in utero due to abnormal placental development, and the EGF receptor is altered in human placentas of intrauterine growth restricted (IUGR) pregnancies. Moreover, EGF promotes trophoblast proliferation and differentiation and inhibits trophoblast apoptosis. HB-EGF is expressed by the placenta throughout human pregnancy, but expression was negligible in pregnancies complicated by preeclampsia and FGR. HB-EGF stimulates EVT proliferation, migration and invasion.

Fig. 2 Proposed interactions of hormonal and nutritional drivers in the control of intrauterine growth. From Sferruzzi-Perri, A. N, Vaughan, O. R., Forhead, A. J., Fowden, A. L. (2013). Hormonal and nutritional drivers of intrauterine growth. *Current Opinion in Clinical Nutrition and Metabolic Care* 16, 298–309

VEGF

The VEGF superfamily is comprised of VEGF-A (known as VEGF), -B, -C, -D, -E and placental growth factor (PlGF). VEGF is encoded from a single gene organized as eight exons and alternative splicing produces 121, 145, 165, 189 and 206 amino acid isoforms. VEGF is a heparin-binding glycoprotein of 45 kDa and a highly potent endothelial cell mitogen that stimulates vascular permeability and consequently new blood vessel formation via angiogenesis. Although new vessel growth and maturation are highly complex processes, VEGF has a critical early rate-limiting role. Thus, VEGF-null mice exhibit vascular defects in embryonic tissues and embryonic lethality.

VEGF binds to the fms-like kinase (Flt-1 or type I) and kinase-insert domain (KDR/Flk-1 or type II) transmembrane tyrosine kinase receptors (Fig. 3, Shibuya, 2013). Both receptors are required for vascular development as Flt-1 or KDR/Flt-1 defective mice die in utero. VEGF-A binds to both receptors and coreceptor neuropilin-1, VEGF-B only binds to the Flt-1 receptor which also binds PlGF. VEGF-C and D bind to Flt-4 or type III and stimulate lymph angiogenesis, while VEGF-E is a KDR/Flk-1 agonist. Flt-1 signaling is important for tumor growth, metastasis and chronic inflammation. A soluble truncated form of the Flt-1 receptor (sFlt-1) which lacks tyrosine kinase signaling, sequesters VEGF and PlGF thereby preventing VEGF interaction with its receptors. VEGF, PlGF and the respective receptors are expressed by placental cytotrophoblasts, syncytiotrophoblast, inner villous stromal cells and decidua cells. VEGF expression in villous cytotrophoblasts and vessel density within the inner villous compartment increase with advancing pregnancy.

Although unproven, VEGF-A may also promote migration and invasion of EVT. Placental expression and serum levels of VEGF and PlGF are lower and the sFlt-1 receptor which sequesters VEGF higher in human preeclampsia and IUGR, adverse pregnancy conditions underpinned by deficient EVT invasion and remodeling of the uterine arteries. Since the Flt-1 promoter contains a hypoxia response element (HRE), the increase in placental hypoxia induced by improper uterine artery remodeling with preeclampsia may account for the increase in expression of placental sFlt-1, which disrupts renal glomerular endothelial cell permeability resulting in proteinuria, a major symptom of preeclampsia. PlGF is expressed as four isoforms, PlGF-1 to -4, as a result of alternative splicing. PlGF may also promote EVT migration/invasive capacity.

EG-VEGF

EG-VEGF is a growth factor expressed only in steroid-producing endocrine glands, that is, ovary, testis, adrenal and placenta. EG-VEGF is mitogenic for endocrine gland endothelial cells and like VEGF induces fenestrations in these cells. However,

Fig. 3 The VEGF and VEGF receptor (R) system. VEGF-A acting via the VEGFR-1 has a central role in angiogenesis, inflammation, and the phenotypes of cancer. Pro-angiogenic signals are also generated from VEGFR-2, whereas sFlt-1 underlies physiological corneal avascularity and symptoms of preeclampsia. Nrp co-receptors for VEGFs increase the affinity between VEGF and its receptors. VEGFxxx, an alternatively processed variant form of VEGF-A, is suggested to be an endogenous competitor against VEGF-A. From Shibuya, M. (2013). Vascular endothelial growth factor and its receptor system: Physiological functions in angiogenesis and pathological roles in various diseases. *Journal of Biochemistry* **153**, 13–19.

EG-VEGF shares no structural homology with VEGF, but rather is structurally related to a family of peptides termed prokineticins, e.g., prokineticin-2 (PROK2). The gene for EG-VEGF is located on chromosome 1p21 and two G-coupled receptors (PROKR1 and PROKR2) bind PROK1 and PROK2 and mediate a cellular response dictated by G-proteins.

EG-VEGF and its receptors are expressed by the placental syncytiotrophoblast and cytotrophoblasts and maternal serum EG-VEGF levels peak in the first trimester then decline in a pattern very similar to that of hCG. Moreover, hCG increases placental EG-VEGF and PROKR2 expression as modulated via CRE-1 and -2. It appears that EG-VEGF suppresses invasive capacity of trophoblasts, although it is unknown whether EG-VEGF plays a physiologic role in this process or exacerbates the placental dysfunction characteristic of adverse conditions of pregnancy, e.g., preeclampsia.

Thus, several of the placental growth factors, acting in an autocrine and/or paracrine manner, appear to control placental villous and extravillous trophoblast function, including EVT migration and invasion. Future research in this area of placental biology is needed to establish the interactive role the placental growth factors have in vivo in regulating human placental development and function.

Steroid Hormones

Estrogens

Synthesis and regulation

The placenta becomes the primary source of estrogen at approximately 8 weeks of human gestation, and serum estrone (E_1), estradiol (E_2) and estriol (E_3) levels progressively increase thereafter (Fig. 1). The placenta lacks the 17α -hydroxylase/ $17-20$ -lyase ($P450_{C17}$) gene required for de novo production of estrogen. However, the fetal and to some extent the maternal adrenal cortex produces C_{19} steroids, particularly dehydroepiandrosterone (DHEA), that are aromatized via $P450_{arom}$ to the estrogens. In the fetal adrenal cortex, DHEA is synthesized de novo from LDL cholesterol, then sulfurylated and transferred to the placenta as DHEAS or, after 16-hydroxylation, as 16-OH-DHEAS (Fig. 4). DHEAS is converted to DHEA and 16-OH-DHEAS to 16 OH-DHEA via a placental sulphatase. DHEA is converted to Δ^4 -androstenedione via 3β -HSD, and an $P450_{arom}$ enzyme encoded by the CYP19A1 gene aromatizes Δ^4 -androstenedione to estrone, testosterone to estradiol, and 16-OH-DHEA to estriol. The interconversion of estrone and estradiol and of Δ^4 -androstenedione and testosterone is catalyzed by the 17β -hydroxysteroid oxidoreductase (17β -HSD). The fetal adrenal cortex by synthesizing DHEA and other C_{19} -steroids has a major role in regulating placental estrogen production. Fetal pituitary ACTH and corticotrophin releasing hormone (CRH) secreted by the placenta stimulate fetal adrenal DHEAS production, and thus indirectly placental estrogen formation. Moreover, cAMP stimulates expression of the $P450_{arom}$ enzyme.

Fig. 4 Estrogen biosynthesis in the fetal-placental unit during human pregnancy. Dehydroepiandrosterone (DHEA); DHEA sulfate (DHEAS); Δ^4 -androstenedione (Δ^4 A); testosterone (T); estrone (E_1); estradiol (E_2); estriol (E_3).

Function

Estrogen has significant roles in preparing the endometrium for implantation, the cascade of events leading to the onset of labor, the maternal cardiovascular changes of pregnancy and preparing the breast for lactation. The placental trophoblast also expresses estrogen receptor α and β , providing a mechanism for estrogen action within this tissue. Thus, the differentiation of human villous cytotrophoblasts into the syncytiotrophoblast is stimulated by estradiol, an effect possibly mediated by leptin. Extravillous trophoblast (EVT) migration to and invasion and remodeling of the uterine spiral arteries, which is extensive during the first trimester of human pregnancy, transforms these arteries into low-resistance vessels to promote blood flow to the placenta and thus development of the fetus. Prematurely elevating estrogen levels in early baboon pregnancy suppresses trophoblast VEGF expression and remodeling of the uterine spiral arteries. It has been proposed (Albrecht and Pepe, 2010), therefore, that the low levels of ovarian estrogen in early pregnancy promote VEGF expression and EVT remodeling of the uterine arteries (Fig. 5), whereas the normal rise in estrogen thereafter suppresses and thus controls the extent to which the uterine vessels are remodeled. This process translates to the human, since the elevated levels of estradiol induced in IVF human pregnancy increase the risk of developing preeclampsia, which is underpinned by a defect in uterine artery remodeling.

During the second half of pregnancy, estrogen stimulates placental receptor-mediated uptake of LDL as cholesterol substrate for and activity of the P450_{scc} enzyme catalyzing the synthesis of progesterone. Moreover, estrogen regulates transplacental cortisol-cortisone metabolism and the levels of cortisol arriving in the fetus, thereby controlling onset of fetal pituitary-adrenal ACTH secretion (Pepe and Albrecht, 1995). Estrogen also downregulates growth of and synthesis of C₁₉-steroid estrogen precursors by the fetal zone of the fetal adrenal cortex, to control estrogen levels within a physiological range. Estrogen also increases fetal pituitary ACTH secretion during ovine pregnancy, and thus the interplay of placental estrogen and the fetal pituitary-adrenal axis may have a role in the initiation of labor. In addition, estrogen promotes formation of the stockpile of healthy ovarian follicles within the human and nonhuman primate fetus that is critical for timely onset of puberty and reproductive function after birth.

Estrogen-deprived pregnant baboons, P450_{arom} or ER α knock-out mice, and P450_{arom}-null humans exhibit a disruption in testis morphology, germ cell, efferent ductile and epididymal development and/or infertility, showing that estrogen also has an essential role in promoting fetal testis development and onset of fertility. Finally, estrogen deprivation in human and baboon pregnancy results in insulin insensitivity and glucose intolerance in the offspring, indicating that estrogen programs mechanisms within the fetus required for normal insulin action after birth.

Fig. 5 Proposed role of low estrogen levels in early primate pregnancy in promoting VEGF expression and extravillous trophoblast (EVT) migration, invasion and remodeling of the uterine spiral arteries.

Progesterone

The placenta also becomes the primary source of progesterone at approximately 8 weeks of human pregnancy and levels increase to 150–175 ng/mL at term (Fig. 1). Although *de novo* synthesis of cholesterol is limited, the receptor-mediated uptake of LDL cholesterol by the placental syncytiotrophoblast accounts for the major proportion of placental progesterone production. Cholesterol is converted to pregnenolone via the P450_{scc} enzyme (CYP11A1 gene) within the mitochondria. P450_{scc} functions as a terminal oxidase, in which electrons from NADPH are accepted by an adrenodoxin reductase flavoprotein that transfers the electrons to an iron–sulfur protein, adrenodoxin, that donates the electrons to cytochrome P450_{scc}. The conversion of pregnenolone to progesterone is catalyzed by 3 β -HSD, which is in excess, while the reduction of adrenodoxin is rate-limiting for progesterone synthesis. cAMP chronically stimulates expression/activity of P450_{scc}, adrenodoxin, and LDL receptors in a dose-dependent manner in human cytotrophoblasts, an effect that requires the catalytic unit of protein kinases which may regulate gene transcription.

Progesterone has an essential role in promoting endometrial decidualization, implantation, and glandular function in the early establishment of pregnancy. Progesterone signaling through progesterone receptor isoforms A and B, as modulated by COUP-TFII nuclear receptor and Hand 2 transcription factor, is critical for decidualization and implantation. Progesterone also suppresses the maternal immune system and inflammatory processes at the maternal-fetal interface to promote implantation of the conceptus, and pregnancy maintenance. Progesterone has a pivotal role in repressing myometrial contractility and labor throughout pregnancy. Finally, progesterone is involved in lobuloalveolar proliferation and growth of the mammary gland, but suppresses lactation until after delivery when placental progesterone is lost.

Placental Hypothalamic-Like Neuropeptide and Peptide Hormones

The placenta produces key components of the hormonal systems that characterize the hypothalamic-pituitary axis, including corticotrophic hormone (CRH), urocortin (Ucn), and gonadotropin-releasing hormone (GnRH). The placenta also synthesizes several neuropeptides, e.g., kisspeptin, neuropeptide Y (NPY), oxytocin, neurokinin B (NKB), and vasoactive peptides, e.g., endothelin-1 (ET), adrenomedullin (AM), calcitonin gene-related peptide (CGRP), and parathyroid hormone related peptide (PTHrP) that modulate other hormone systems important to successful pregnancy (Petraglia et al., 2010).

CRH and Ucn

The CRH/Ucn family of peptides is produced in the placental trophoblasts and include CRH, Ucn, Ucn2 and Ucn3. CRH and the Ucn bind to a CRH-binding protein (CRHBP) also synthesized in the placenta. In contrast to the increase in maternal serum levels of CRH with advancing gestation, CRHBP levels decline sharply near the end of gestation, thereby enhancing the bioavailability of CRH and Ucn. CRH and Ucn bind to the CRHR1 and CRHR2 G-protein-coupled receptors expressed in the trophoblast, myometrium, amnion and chorion. Glucocorticoids, estrogen, norepinephrine and prostaglandins increase and progesterone suppresses placental CRH production.

Placental CRH stimulates fetal pituitary ACTH expression and thus fetal adrenal DHEAS and cortisol production in late gestation. CRH may also act directly on placental trophoblast to promote estrogen and decrease progesterone biosynthesis and play a role in coordinating metabolic and neuroendocrine signals between the mother and fetus (Alcantara-Alonso et al., 2017). Since the elevation in CRH is more rapid in women who deliver preterm and slower in those who deliver late, it has been proposed that

CRH acts as a biologic clock to control the length of gestation and thus the timing of birth. Ucn2 acting via CRHR2 regulates the signaling pathway, myosin light chain phosphorylation, and calcium-activated potassium channels in the human myometrium, which would promote labor activity.

Maternal serum CRH levels are increased and CRHBP decreased in pregnancies complicated by preeclampsia and preterm labor and thus their levels may be predictive of these conditions. CRH in high level can also act on vascular smooth muscle to increase peripheral vasodilation and thus lower arterial blood pressure and vascular tone within the uteroplacental circulation. CRH and Ucn stimulate placental pro-opiomelanocortin (POMC) processing and thus expression of ACTH, β -endorphin and melanocyte stimulating hormone (α -MSH). The placenta also synthesizes the opioid peptides, enkephalin, dynorphins 1–8 and 1–13 and β -endorphin, although the specific role of these opioids on placental function remains to be elucidated.

GnRH

GnRH, typically expressed by the hypothalamus, is also synthesized as isoforms GnRH-I and -II by the human placental trophoblast. Both isoforms signal via activation of the GnRH receptor-1 which is localized to cytotrophoblasts, syncytiotrophoblast and the decidua. Although levels of GnRH remain relatively constant during gestation, placental GnRH-1 expression mirrors that of β hCG. As in the hypothalamus, depolarizing and cAMP stimulatory agents, activin A, and estrogen stimulate placental GnRH secretion. Placental GnRH, notably GnRH-1, is a major regulator of β hCG. GnRH may also have a role in decidualization in early pregnancy, since it induced apoptosis in human decidua stromal cells, and in EVT invasion via modulation of matrix metalloproteinases.

Kisspeptin

Kisspeptins comprise a family of proteins derived from the Kiss-1 gene which when transcribed yields Kiss-1, which is further transformed to additional kisspeptins. Kiss-1 is expressed by the placental syncytiotrophoblast, cytotrophoblasts and decidua. The kisspeptin G protein coupled receptor, GPR54, is expressed in the human hypothalamus and the placenta. Placental Kiss-1 and receptor levels are elevated in the first trimester and in preterm and preeclampsia pregnancies, while plasma kisspeptin levels show a progressive rise during normal pregnancy.

Kisspeptin affects GnRH neuronal excitability and expression and thus influences the hypothalamic-pituitary-gonadal axis and puberty onset. Subjects with GPR54 null mutation exhibit idiopathic hypogonadotropic hypogonadism. Kiss-1 also inhibits trophoblast migration and placental trophoblast kisspeptin expression is low in women with a history of recurrent miscarriage.

NPY

NPY is expressed in the decidua, fetal membranes and placental trophoblast, as well as the central and peripheral nervous system. Maternal serum NPY levels are relatively constant during pregnancy. The two NPY receptor subtypes, NPY1R and NPY3R, are localized to placental syncytiotrophoblast microvilli. NPY appears to stimulate placental CRH synthesis and release by modulating the phospholipase C/inositol triphosphate receptor axis and calcium calmodulin kinase II activity. NPY may also stimulate food intake, inhibit insulin release, modulate gastrointestinal motility and events leading to labor, although its roles in these processes are not clearly defined.

Oxytocin

In addition to its synthesis within the hypothalamus, oxytocin is also produced in placental syncytiotrophoblast, decidua, amnion and chorion. Because oxytocin levels are much greater in the placenta than in the posterior pituitary, the placenta appears to be a major source of maternal circulating oxytocin. Maternal serum oxytocin concentrations are highest at night coinciding with nocturnal spontaneous uterine activity and labor. Estrogen appears to be a major regulator of oxytocin expression, particularly in decidua and chorion. Placental oxytocin expression is also increased by placental CRH, activin and prostaglandins, factors integral to the cascade of events leading to parturition. The oxytocin receptor is expressed in the myometrium, decidua and chorion leavies, where levels are increased by estrogen and decreased by progesterone and may have a role in the onset of labor.

NKB

The placenta also expresses NKB, which belongs to the tachykinin family of signaling peptides, such as substance P, that function in the central nervous system as excitatory neurotransmitters for nociception. The G-protein-linked NKB receptors (NKBR 1–3) are expressed in human placenta and umbilical vein endothelial cells. NKB or NKB receptor-3 mutation causes normosmic isolated hypogonadotropic hypogonadism, indicating the role of NKB in human reproductive function and development. NKB also modulates water homeostasis, pulmonary inflammation, cognition, and placental vasodilation via a receptor-mediated mechanism independent of nitric oxide.

ET

ET is synthesized as three isoforms, ET-1-3, expressed by placental endothelial cells, villous trophoblast, amniotic epithelium, as well as fetal-placental vessels. ET-1 is a potent vasoconstrictor of the human placental vasculature and thus appears to play a role in control of uteroplacental blood flow. Placental ET-1 expression and circulating levels are higher in women with preeclampsia.

AM

AM is a 52 amino acid peptide expressed in syncytiotrophoblast, villous cytotrophoblast, EVT and the decidua. Maternal AM levels are 3-fold higher in pregnant than nonpregnant women and increase during the course of human gestation. AM null mutation in mice results in fetal death at midgestation caused by cardiovascular defects. Administration of an AM antagonist caused fetal growth restriction and defective blood vessel development in the placenta, suggesting a role in placental vascularization.

CGRP

CGRP is a 37 amino acid neuropeptide expressed in the placental syncytiotrophoblast, villous vascular endothelial cells, and decidua. CGRP is secreted into the maternal circulation where levels progressively increase with advancing gestation. CGRP binds to a G protein-coupled receptor, which is modified by receptor activity modifying proteins (RAMP-1-3) and is localized to the placental syncytiotrophoblast microvillous and basal membranes, and the myometrium. CGRP receptor-null mice exhibit cardiovascular defects and embryonic death at midgestation, indicating the importance of CGRP for fetal development. A major function of CGRP in pregnancy appears to be modulation of uteroplacental vasoactive tone. Moreover, CGRP promotes human vascular endothelial cell proliferation and migration and capillary-like tube formation, suggesting that CGRP has a role in placental angiogenesis and neovascularization.

PTHrP

PTHrP is a 141 amino acid protein which shares sequence homology with PTH and is enzymatically processed to PTHrP 1–34 and 67–86. PTHrP1–34 is expressed in the syncytiotrophoblast and PTHrP 67–86 in placental villous capillary endothelial cells. Maternal serum levels of PTHrP are elevated in pregnancy particularly in late gestation. PTHrP binds to the PTH receptor expressed in the placenta and myometrium. PTHrP-deficient mice exhibit a reduced maternal-fetal calcium gradient, skeletal dysplasia and die at birth. PTHrP also elicits a potent vasodilatory effect on the uteroplacental circulation and inhibition of uterine contractility.

Adipokines

Adipokines comprise a group of peptides, including leptin, adiponectin, resistin and ghrelin, that play an important role in the metabolic adaptations of human pregnancy, notably the increase in maternal insulin resistance with advancing gestation. Although originally isolated from adipose, adipokines are also expressed by the placenta.

Leptin

Leptin is a 146 amino acid protein that regulates food intake, energy expenditure and metabolism and thus body weight. Leptin action is modulated by the leptin receptor, a member of the cytokine receptor superfamily. Differential splicing of the leptin receptor results in four isoforms characterized by the length and sequence of the cytoplasmic terminal and classified as long (HLR_L) or short (HLR_S). In addition to maternal tissues, amnion, chorion and umbilical vasculature express HLR_L and HLR_S.

Leptin is expressed by the placental syncytiotrophoblast and cytotrophoblast as well as adipose. Maternal serum leptin concentrations rise throughout pregnancy, peaking during the second and third trimester. Placental leptin expression appears to be regulated by the hormonal *milieu* of pregnancy and not by trophoblast mass. Leptin is encoded by the *lep* gene located on chromosome 7q31 and transcription in adipose is increased by estradiol, glucocorticoids, and insulin and decreased by β -adrenergic agonists. Consensus half sites for estrogen receptor and a hypoxia response element in the promoter contribute to leptin transcription. Tissue-specific regulation of leptin expression is also known to be epigenetically mediated through DNA methylation at a tissue-specific region in the *lep* gene promoter. The degree of methylation of the *lep* gene in the placenta may play an important role in leptin expression in normal pregnancy, as well as in pregnancies complicated by FGR, diabetes and preeclampsia.

In addition to regulation of satiety, leptin has other metabolic functions, including the suppression of pancreatic β cell insulin secretion, enhancement of adipocyte glucose utilization and lipolysis, and increase in insulin sensitivity. Importantly, the primary physiologic role of leptin to suppress food intake is reduced during pregnancy, apparently to assure nutrient availability for fetal growth and maternal metabolic homeostasis (Schanton et al., 2017). The hyperphagia of pregnancy is caused by leptin resistance and disruption of the leptin receptor signaling pathway in the hypothalamus and/or changes in placental PL secretion. In addition to effects on maternal tissues, leptin modulates aspects of placental function, including stimulation of trophoblast proliferation and syncytiotrophoblast amino acid transport activity critical to fetal growth.

Adiponectin

Adiponectin is a 248 amino acid protein that enhances insulin sensitivity and reduces hepatic glucose production. Although this metabolic hormone is abundantly produced by adipose, the placenta also expresses adiponectin. The full length protein (fAD) can multimerize to form several low, medium and high molecular weight complexes. The adiponectin receptors, ADIPO-R1 and -R2, are expressed in multiple tissues, including skeletal muscle, liver and the placenta. In humans, maternal serum adiponectin

levels are elevated very early in gestation and then decline and remain relatively constant throughout the remainder of pregnancy. In contrast, adiponectin levels in the fetus are markedly increased and correlated with gestational age. In addition to enhancing insulin sensitivity, adiponectin may have a role in promoting fetal growth, and stimulating trophoblast hCG expression.

Resistin

Resistin is comprised of two 92 amino acid disulfide-linked polypeptides and expressed by placental syncytiotrophoblast. Maternal serum resistin levels are relatively constant in the first and second trimester, then increased by the third trimester. In conjunction with placental lactogen, resistin is thought to play an important role in the marked increase in insulin resistance with advancing gestation. The factors controlling expression of the gene encoding resistin, which is localized to chromosome 19p13.2, remain to be elucidated.

Ghrelin

Ghrelin is a 28 amino acid peptide hormone produced by the intestine, pancreas, kidneys and the placenta. Once in blood, ghrelin is deacylated by enzymes to form des-acyl-ghrelin (DAG) which accounts for 90% of the hormone circulating in plasma. DAG acting via pathways yet to be identified stimulates adipogenesis. Importantly, hyperglycemia and insulin resistance are independently associated with a decrease in ghrelin expression. Maternal serum ghrelin levels and placental expression are highest in early-midgestation then decline thereafter. The factors regulating placental ghrelin expression are unknown, however, women carrying the 51Q allele of the ghrelin gene have a fivefold lower risk of developing gestational diabetes. The protective effect of 51Q may reflect decreased levels of ghrelin which would facilitate increased pancreatic insulin release.

Thus, with advancing gestation placental expression and maternal serum levels of leptin and resistin increase, while adiponectin and ghrelin levels decrease, a pattern of expression that would promote maternal satiety and decrease insulin sensitivity to ensure adequate maternal nutrient (e.g., glucose) supply to the fetus for growth and maternal adipose deposition for metabolic homeostasis. Leptin and adiponectin may also regulate aspects of trophoblast function, including expression and activity of nutrient transporters important to fetal growth. Moreover, placental expression and maternal serum concentrations of leptin are elevated in pregnancies complicated by preeclampsia, particularly in the presence of a small fetus, apparently as a compensatory response to an under-perfused placenta.

In summary, the placenta produces a wide range of protein and steroid hormones, as well as hypothalamic-like neuropeptides and adipokines that have important roles in regulating pregnancy maintenance, placental and maternal vascular development, fetal growth, and metabolic pathways that control maternal and fetal homeostasis and mechanisms that coordinate maturation of fetal organ systems important for function in adulthood. A major challenge in future investigation is to establish how these placental peptide and steroid hormones interact to control these critically important aspects during pregnancy and prenatal and postnatal development.

Introduction

While the importance of pituitary-derived growth hormone (GH) and prolactin (PRL) in postnatal growth and lactogenesis is well documented, their role in fetal growth and development has been more controversial. The lack of effect of anencephaly or congenital absence of the pituitary gland on human fetal growth rate led to the conclusion that fetal development occurs independent of fetal pituitary-derived GH. Yet, infants with GH receptor (GHR) dysfunction exhibit clinical in utero growth restriction, suggesting that GH or a GH “analog” may have actions within fetal tissues. Indeed, members of the GH/PRL gene family are produced by the placenta, which may have common functions providing sufficient redundancy to enhance the likelihood of an optimal pregnancy outcome.

Of the members of the ancestral GH/PRL gene family transcribed in the placenta, the placental lactogens (PL) or chorionic somatomammotropin (CSH) is produced by most eutherian mammals, with the notable exception of the horse and pig. Human CSH was initially purified by two groups in 1961 and 1962 and was later shown to exhibit $\approx 85\%$ amino acid sequence identity with human GH. By contrast, nonprimate CSHs appear to have evolved from the ancestral PRL gene. Placental and circulating concentrations of CSH are reduced in human and sheep intrauterine growth-restricted (IUGR) pregnancies. However, whether this is a cause or an effect of IUGR has not been determined, and as will be discussed, the exact function of CSH in any species has not been fully elucidated. For obvious ethical reasons, a thorough examination of the function of CSH in human pregnancy is not feasible, predicating the need for relevant animal models.

Gene Organization and Biochemical Characteristics

Human CSH evolved from the ancestral GH gene, explaining its 87% amino acid sequence homology with GH, and the genes encoding CSH reside within a five gene cluster on chromosome 17 (Walker et al., 1991). This gene cluster includes, in order, *GH1* (GH-N), *CSHL1* (CS-L or PL1), *CSH1* (CS-A or PL4), *GH2* (GH-V), and *CSH2* (CS-B or PL3). *GH1* is expressed by somatotropes of the anterior pituitary, whereas *GH2* is expressed by syncytiotrophoblast cells of the placenta and is secreted only into the maternal circulation and not the fetal circulation. Of the CSH genes, both *CSH1* and *CSH2* are actively transcribed by the syncytiotrophoblasts, and the proteins encoded by these genes only differ by one amino acid within the signal peptide, such that the mature secreted CSH1 and CSH2 are identical nonglycosylated proteins. By contrast, *CSHL1* is often considered a pseudogene due to complex transcript splicing events, predicting that the majority of processed *CSHL1* mRNA is nonfunctional. While the “upstream” flanking regions of *GH1*, *CSH1*, and *CSH2* genes share significant sequence homology, there are specific differences that appear to impede the transcription of the CSH genes by pituitary somatotropes. Syncytiotrophoblast-specific transcriptional regulation of *CSH1* and *CSH2* appears to reside with enhancer elements located distal to the *CSH2* gene, and the proteins binding these enhancer elements may be required for nucleation of the preinitiation complex leading to trophoblast-specific transcription (Walker et al., 1991). More recent evidence indicates transcription of these placental genes is enhanced when the locus control region and the local enhancer and promoter elements undergo DNA demethylation and histone hyperacetylation.

All nonprimate CSH genes appear to have evolved from the ancestral PRL gene rather than the GH gene, and as such, the genes encoding nonprimate CSH are located on the same chromosome as PRL. With mice and rats (Soares et al., 2007), each express two different PLs/CSHs: PL-I (*Prl3d*, *Csh1*) and PL-II (*Prl3b*, *Csh2*). There are at least three distinct *Prl3d* genes and one *Prl3b* gene, located on the same chromosome as *Prl*, as well as several proliferin (*Plf*) genes and approximately 20 PRL-like protein genes expressed by the placenta. Interestingly, all three rodent PL-I (Prl3d) are glycoproteins, whereas PL-II (Csh2) is not glycosylated. As with rodents, CSH in cattle and sheep also evolved from the ancestral PRL gene. In cattle, there is a single CSH (*CSH2*) gene located on chromosome 23 with the PRL gene and a number of genes encoding prolactin-related proteins (*PRP*) produced by the placenta. Sheep are similar in that there is a single CSH (*CSH*) gene located on chromosome 20 with the PRL gene, and several *PRP* genes expressed by the placenta. Cattle and sheep CSHs (Anthony et al., 1995) share $\approx 50\%$ amino acid sequence identity with their respective PRL and only $\approx 24\%$ with their respective GH. Cattle CSH exists as multiple glycosylated isoforms, whereas sheep CSH exists as a single nonglycosylated polypeptide. Furthermore, cattle and sheep CSHs are only $\approx 66\%$ identical in their amino acid sequences, whereas the amino acid identity for GH or PRL between these species is $\approx 99\%$. The divergence in the structure of cattle and sheep CSHs could infer adaptive evolutionary pressure on these genes expressed by the placenta.

Secretion and Receptors

Human CSH is detectable in the placenta by 18 days of gestation (dGA), can be detected in maternal circulation by 21 dGA, and increases exponentially during the first trimester and then more gradually until term, reaching values of 5–10 $\mu\text{g/mL}$ in maternal circulation (Fig. 1). In contrast to placental-derived GH (GH2), CSH is secreted into the fetal circulation, and while the available

Fig. 1 Human maternal and fetal plasma CSH concentrations. Maternal plasma CSH is represented by the *solid gray line*, and fetal plasma CSH is represented by the *black circles*. Information derived from Handwerger (1991) and Handwerger and Freemark (2000).

data is minimal, the CSH concentration in fetal plasma at 20 weeks of gestation is approximately 5 ng/mL and at term is approximately 20–30 ng/mL. Prior to week 6 of gestation, the cytotrophoblasts of the developing placenta appear to be the site of CSH production, whereas during the remainder of gestation, the syncytiotrophoblasts are clearly the site of CSH production. The amount of CSH mRNA within individual syncytiotrophoblasts does not appear to change during the course of pregnancy, but the amount of syncytiotrophoblast tissue within the placenta increases as gestation progresses, which could explain the fivefold increase in CSH mRNA concentration between the first and last trimester. From these data, one may infer that CSH is constitutively expressed following syncytiotrophoblast formation, and its synthesis may not be subject to a great deal of regulation. However, a variety of growth factors, secretagogues and metabolic regulators, have been implicated in the regulation of CSH secretion, but no clear regulatory control has been established. As noted earlier, there are several reports demonstrating significant reductions in the concentration of CSH in maternal circulation of IUGR pregnancies. As yet, there is no direct evidence in the human to decipher whether or not this is just a function of reduced placental mass associated with IUGR or is playing a more causative role.

A unique CSH receptor has yet to be isolated or structurally characterized in humans. While CSH shares $\approx 85\%$ amino acid sequence identity with pituitary-derived GH (GH1), CSH exhibits low affinity for the GHR, but both CSH and GH exhibit high-affinity binding to the PRL receptor (PRLR). Interestingly, both CSH and GH bind the PRLR with greater affinity than does PRL itself, whereas PRL does not bind the GHR. In maternal tissues, it may well be that CSH exerts its actions through either the GHR or PRLR or both. However, in human fetal tissues, the limited available studies lend credence to the likelihood of a “unique” CSH receptor. Specific binding of GH to fetal liver microsomes has been demonstrated, but no specific binding was apparent with fetal skeletal muscle microsomes. There was specific binding of CSH to microsomes derived from both fetal tissues. Furthermore, the GH binding sites in the fetal liver exhibited sixfold greater affinity for GH than for CSH, and the CSH binding sites exhibited a ninefold greater affinity for CSH than for GH. The differences in relative affinity for GH and CSH with fetal liver microsomes, coupled with the lack of specific GH binding to fetal skeletal muscle microsomes, suggest that their respective binding sites or receptors are different. This conclusion is supported by the fact that GHR can be immunolocalized in the fetal liver, but not fetal skeletal muscle.

With mice and rats, during essentially the middle third of gestation, Prl3d is produced by polyploid trophoblast giant cells of the developing placenta, followed by the expression and secretion of Prl3b by trophoblast giant cells during the last third of gestation. Both Prl3d and Prl3b are PRLR receptor agonists. In domestic ruminants, CSH is produced by chorionic binucleate cells (BNCs). These are thought to be derived from endoreduplication without cytokinesis of the chorionic epithelium and begin to arise within the trophoctoderm layer during conceptus elongation during the establishment of pregnancy. During most of gestation, BNC comprise approximately 25% of the chorionic epithelium, and at any given point in time, approximately 20%–25% of the BNCs are actively migrating to fuse with the maternal–fetal syncytium. In domestic ruminants, the syncytium initially arises from the fusion of BNC with maternal uterine epithelial cells, forming syncytial plaques. However, as gestation progresses in cattle, the maternal–fetal syncytium is lost, with reestablishment of the maternal uterine epithelium. Consequently, BNCs fuse with maternal epithelial cells, forming trinucleated cells. By contrast, sheep BNCs continue to migrate and fuse with the established syncytium, and as pregnancy progresses, the uterine luminal epithelium is lost, and the syncytium becomes predominantly of “fetal origin.” The difference between these two ruminant species in the retention of a functional maternal–fetal syncytium is also reflected in the concentration of CSH in both maternal and fetal circulation. In cattle, the concentration of CSH in maternal blood is quite low, with values typically not exceeding 2 ng/mL throughout gestation. By contrast, sheep CSH has similar maternal concentration profiles with human CSH, increasing steadily throughout gestation (Fig. 2), and becomes quite variable during late gestation, often reaching concentrations exceeding 1 µg/mL (Kappes et al., 1992). The concentration of maternal sheep CSH is correlated to placental CSH mRNA concentrations, and the gestational increase is reflective of increasing total BNC in the sheep placenta; as placental mass plateaus during the second third of gestation, the placenta continues to restructure by adding proportionately more chorionic epithelium. In cattle, fetal concentrations of CSH are greatest (25–30 ng/mL) at the end of the first trimester and decline to 5–10 ng/mL near term. In sheep, fetal CSH concentrations increase during the first two-thirds of gestation but then plateau at concentrations of 30–60 ng/mL during late gestation (Fig. 2). The plateau in fetal concentrations can be misinterpreted, as the entry rate kinetics into the umbilical circulation increases during this time frame but is offset by increasing fetal blood volume.

Fig. 2 Maternal and fetal plasma CSH concentrations in sheep. Maternal plasma CSH is represented by the solid gray line, and fetal plasma CSH is represented by the solid black line. Information derived from Kappes et al. (1992).

As noted earlier, rodent Prl3d and Prl3b are PRLR agonists, but the exact receptor through which ruminant CSHs elicit their actions is less clear. GHR and PRLR radioreceptor assays were the basis for monitoring the purification of ruminant CSH, yet in competitive binding assays, GH has greater affinity for the GHR than does CSH, as is also the case with PRL and the PRLR. Both cattle and sheep CSHs have been shown to specifically bind the GHR, but they do so in a 1:1 stoichiometry rather than the 1:2 stoichiometry of binding that GH and GHR exhibit. Dimerization of the GHR (i.e., 1:2 stoichiometry of binding) is required to elicit downstream signaling from this receptor, and the evidence at hand suggests that ruminant CSH and its 1:1 binding of the GHR is acting as a functional antagonist to GH. However, cattle and sheep CSHs have been shown in vitro to heterodimerize the GHR and PRLR, activating downstream signaling. The heterodimerization of the GHR and PRLR may well account for CSH actions, at least within maternal tissues. As noted with human CSH, there is evidence within the fetus for a “unique” or specific CSH receptor. In fetal sheep, while *GHR* mRNA is transcribed throughout most of gestation in the fetal liver, the transcript is derived from one of several alternate exon 1’s, all of which encode an autonomous short-open reading frame upstream of the normal “start” codon, which resides in exon 2. Consequently, it is unlikely that a functional GHR is translated, until near term, when fetal cortisol appears to induce “normal” splicing of exon 1A in the *GHR* transcript. Additionally, while the *PRLR* gene is transcribed in the fetal liver, its expression is quite low. More importantly, saturation analysis of fetal sheep liver microsomes demonstrated specific saturable binding kinetics for CSH from 60 dGA through near term but no specific saturable binding kinetics for either GH or PRL. If CSH exerts its actions through the heterodimerization of GHR and PRLR in sheep fetal liver, that would require both GHR and PRLR to exist in the fetal liver and should have provided for specific saturable binding of GH and PRL. It would therefore appear that at least within the human and sheep fetus, CSH may exert its actions through a structurally characterized receptor.

Biological Actions

While we have known of the existence of CSH for nearly 60 years, as yet, the exact biological actions of CSH have yet to be clearly defined. Especially within maternal circulation in humans and sheep, the concentration of CSH is extremely high relative to the reported binding affinity for any receptor, such that infusion of CSH into maternal circulation is not likely to yield tangible/interpretable results. This is also somewhat true within the fetus as well, but at least one study demonstrated discernible effects from chronic infusion of CSH into the sheep fetus. CSH in maternal circulation is depressed in both human and sheep IUGR pregnancies, but it has not been ascertained whether this is a mediator of IUGR or simply an effect of reduced placental mass. There are case reports of patients with deletions within the human *CSH1-GH2-CSH2* gene cluster, with varying neonatal outcomes, both supporting and refuting an important role of CSH during pregnancy. In many cases, the phenotype was not adequately characterized, and it is not known if other hormones may have been upregulated in a compensatory fashion. While homologous recombination has been in use to generate specific gene knockouts in mice for about 30 years, as yet, neither Prl3d nor Prl3b have been functionally ablated to determine the resulting phenotype. The recent use (Baker et al., 2016) of in vivo RNA interference of CSH in sheep could provide the means to directly assess the function of CSH in vivo.

Maternal Effects

While responses to CSH in maternal circulation likely vary between humans, rodents, and ruminants and may reflect the receptor(s) through which it acts, CSH has been implicated in modifying maternal metabolism, ovarian steroidogenesis, and mammaryogenesis. The most abundant evidence, derived from both humans and ruminants, is in support of CSH effects on maternal metabolism and will be the focus of this discussion. During the third trimester of human pregnancy, when maternal CSH concentrations are quite high, basal- and glucose-stimulated insulin secretion increases, some tissues become insulin resistant, glucose tolerance is impaired, lipid mobilization is increased, and maternal concentrations of insulin-like growth factor 1 (IGF-1) increase markedly, leading Handwerger (1991) to postulate that these changes in maternal metabolism may result from CSH actions (Fig. 3). All of these

Fig. 3 Predicted biological actions of CSH within the mother. Representation of the various hypothesized effects of CSH within the maternal system during pregnancy. These include the stimulation of IGF-1 and insulin secretion, enhanced peripheral insulin resistance, and increased lipolysis. Conceptually adapted from Handwerger, S. (1991). Clinical counterpoint: the physiology of placental lactogen in human pregnancy. *Endocrine Reviews* 12, 329–336.

changes in maternal metabolism are thought to provide more glucose for placental transport and utilization by the fetus as its primary energy source.

In vitro-derived data from rats and humans support the hypothesis that CSH promotes maternal insulin resistance and β -cell proliferation, with CSH augmenting insulin secretion from adult human pancreatic islets. However, the ability of human CSH to augment glucose-stimulated insulin secretion has varied among experiments, as has the impact of CSH on glucose tolerance. The variability in the response to CSH has also been observed in sheep. An 8 h infusion of sheep CSH into fasting pregnant ewes resulted in reduced plasma glucose and elevated plasma insulin, whereas a 36 h infusion resulted in elevated plasma glucose and reduced plasma insulin. A short-term (12 h) immunoneutralization of maternal CSH did not impact glucose utilization, but did increase plasma insulin concentrations. These three reports differ in their experimental approach, the purity of CSH used and gestational age, making it difficult at best to draw conclusions. In cattle, administration of CSH during pregnancy had no effect on maternal plasma glucose or insulin. With the recent CSH-deficient sheep pregnancies, Baker et al. (2016) reported no effect on maternal glucose concentrations, but did observe a 57% increase in maternal insulin concentrations and a 50% increase in the insulin/glucose ratio. These results agree with the short-term PL immunoneutralization study, both countering the hypothesis of CSH augmenting maternal insulin resistance. Unfortunately, none of these studies exploited the advantage of pregnant sheep as an experimental model, that being the ability to chronically catheterize both maternal and fetal vasculature, and conduct steady-state physiological assessment of insulin/glucose homeostasis. Maternal hyperinsulinemic-euglycemic clamp studies in control and CSH-deficient pregnancies would provide a steady-state well-controlled assessment of CSHs impact on maternal insulin sensitivity.

During late gestation, there is increased lipolysis, providing free fatty acids (FFA) to be used as a maternal energy source during fasting or for building energy stores during nonfasting periods. Studies examining the effect of CSH on lipid metabolism in humans generally support the concept that maternal CSH is lipolytic (Fig. 3). Human CSH increases basal lipolysis in vitro, and administration of CSH in vivo increased the circulating concentrations of FFA, ketones, and glycerol, although these in vivo effects have not been observed in all studies. Esterification of FFA into triglycerides within human adipose is promoted by insulin-stimulated glucose uptake, and this effect is enhanced by treating adipose tissue with CSH in vitro. As with the impact of sheep CSH administration on insulin and glucose homeostasis, there are contrasting results on the impact of CSH on circulating FFA. The short-term

CSH immunoneutralization studies in sheep resulted in a tendency for reduced plasma FFA, agreeing with the potential lipolytic effects of human CSH. However, treating adipose tissue obtained from pregnant sheep with CSH did not result in increased lipolysis. Administration of CSH to pregnant cattle did not impact plasma FFA. While interpreting the effects of CSH on maternal lipolysis and/or lipid deposition in adipose across these species, it should be kept in mind that cattle and sheep are ruminants, and while lipid metabolism pathways are similar with humans, the composition and concentration of circulating FFAs can be quite different between humans and ruminants.

While maternal plasma IGF-1 increases during late gestation when CSH concentrations are high in human maternal plasma, there is no direct evidence that human CSH in fact induces IGF-1 synthesis and secretion, and it may well be that the increase in IGF-1 results from increased concentrations of placental GH (CSH2; GH-V). In cattle, administration of CSH during pregnancy resulted in increased maternal plasma IGF-1 and insulin-like growth factor 2 (IGF-2). However, liver *IGF-1* mRNA concentrations in pregnant ewes were not impacted by a 7-day administration of CSH during the last third of gestation. This lack of effect of CSH administration on liver *IGF-1* expression in pregnant sheep is supported by the lack of effect on maternal liver *IGF-1*, *IGF-2*, IGF-binding protein (*IGFBP1*, *IGFBP2*, and *IGFBP3*) mRNA concentrations, and IGF-1 concentrations in maternal blood in CSH-deficient pregnancies (Baker et al., 2016). The absence of response in sheep, contrasted with a significant enhancement in maternal IGF-1 in cattle, may be influenced by the relative concentrations of CSH in maternal circulation (high in sheep and low in cattle), such that pregnant cattle might respond more robustly to maternal CSH administration due to the low endogenous CSH concentrations. As discussed later, there is considerably more evidence of CSH stimulating IGF production within the fetus.

Fetal Effects

There has been considerable interest in potential CSH anabolic effects in the fetus (Fig. 4), at least in part due to the concept that fetal GH may not be exerting the same growth-promoting effects that it does during postnatal life. This concept was augmented with the demonstration that sheep CSH stimulated ornithine decarboxylase activity, amino acid uptake, IGF-2 secretion, and glycogen synthesis by fetal rat tissues, albeit recognizing that sheep CSH would not have been activating its normal receptor in these studies. However, the effect of sheep CSH on fetal hepatocyte incorporation of glucose into glycogen has since been confirmed using fetal sheep hepatocytes. Furthermore, human CSH has been shown to stimulate uptake of amino acids, DNA synthesis, and IGF-1 production by human fetal fibroblasts, hepatocytes, and myoblasts. With all of these in vitro endpoints, while CSH acted in

Fig. 4 Predicted biological actions of CSH on the placenta and fetus. Representation of hypothesized effects of CSH on the fetus and placenta. Long-held hypotheses (Handwerger, 1991) on CSH stimulation of fetal IGF-1 and insulin during late gestation were supported by the recent results of Baker et al. (2016), which also revealed impacts on placental growth and function.

a dose-responsive fashion, in general, GH was without or had minimal effect, as compared with CSH. In vivo, a 14-day infusion of CSH into the sheep fetus resulted in greater plasma IGF-1 and fetal liver glycogen accumulation, supporting the conclusions drawn from the previous in vitro experiments. The strongest in vivo support for the concept that CSH could have direct growth-promoting effects in the fetus was provided by the recent CSH-deficient sheep pregnancies reported by Baker et al. (2016). Near-term (135 dGA) fetal weight was 32% less in the CSH-deficient pregnancies and was associated with an 83% reduction in fetal liver IGF-1 mRNA concentrations and a 62% reduction in umbilical artery IGF-1 concentrations. Additionally, reductions in fetal liver IGF-2 (71%), IGFBP2 (74%), and IGFBP3 (81%) mRNA concentrations were reported for the near-term CSH-deficient pregnancies.

It had also been hypothesized (Handwerger and Freemerk, 2000) that CSH could stimulate fetal insulin production. This hypothesis was based on the report that human fetal pancreatic explants treated with CSH exhibited significantly greater insulin content and glucose-stimulated insulin release. This in vitro study is supported by the 49% reduction in umbilical artery insulin concentrations observed in near-term CSH-deficient sheep pregnancies (Baker et al., 2016). However, definitive assessment of the impact of CSH deficiency on fetal pancreas development, insulin secretion, and insulin sensitivity awaits in vivo determination of umbilical uptakes and utilization of glucose, steady-state concentrations of fetal insulin, in vivo and in vitro fetal islet insulin secretion, and measurements of islet size, structure, and β -cell mass.

The sheep CSH-deficient pregnancies (Baker et al., 2016) also revealed a previously unrecognized effect of CSH, that being placental growth and function. The placentas of CSH-deficient pregnancies were 52% smaller near term (135 dGA), which likely also contributed to the IUGR observed in these pregnancies. However, we (Jeckel and Anthony) have unpublished data demonstrating that significant IUGR is apparent at the end of the first third of gestation (50 dGA) in CSH-deficient sheep pregnancies. At this stage of gestation (50 dGA), placental size was not significantly reduced, although there were significant reductions in the expression of glucose transporters and IGF, with even greater reductions in the expression of IGFs and glucose transporters near term (135 dGA). While the significance of these findings awaits steady-state assessment of placental glucose transport capacity in vivo and experiments alluded to earlier, we hypothesize (Fig. 4) that during early to midgestation CSH may impact fetal growth by stimulating placental glucose transfer capacity but that during the latter half of gestation, it has additional direct anabolic effects on the fetus by stimulating hepatic IGF-1 production, β -cell proliferation, and insulin production.

Pregnancy Associated Glycoproteins

Overview

Pregnancy-Associated Glycoproteins (PAGs) are products of a gene family expressed by placental trophoblasts of mammals in the Cetartiodactyla order (Wallace et al., 2015). PAGs are thought to have arisen from duplication and subsequent expansion of a pepsin F-like ancestral gene, that itself appears to have been a duplication of Pepsin A (Hughes et al., 2003). The PAGs, pepsin F and pepsin A all belong to a class of proteolytic enzymes known as aspartic proteinases. The products of the PAG gene family are abundantly expressed by placental trophoblasts, and the expression of individual PAGs does change during the course of pregnancy (Green et al., 2000; Touzard et al., 2013). In ruminant ungulates, PAG expression is often cell-specific. Most members of the PAG family in ruminants are expressed predominantly in giant binucleated trophoblast cells (GBCs). Because of their production by GBCs, many of these PAGs can enter the blood circulation of pregnant females. There are other ruminant PAGs that are expressed in only mononucleated trophoblasts or are localized to both trophoblast populations. Transcripts for some PAGs expressed in mononucleated trophoblasts are detectable early in conceptus development and remain detectable in placenta until term, even though relative transcript abundance often varies throughout gestation (Green et al., 2000; Patel et al., 2004; Touzard et al., 2013).

Several sequenced genomes are available for cetartiodactyls, which provides an opportunity to evaluate the number and type of PAGs across the even-toed ungulates. Based on available genome data, the number of PAGs present in each suborder varies from none or a few (in camelids and cetaceans), to more than thirty in the small ruminants. Although the PAGs have been studied extensively for the past three decades, there is no known function for this expansive family. The following chapter summarizes some of the salient features of this gene family expressed by cattle, sheep, swine and related species.

PAGs Are Aspartic Proteinases

The PAGs belong to the aspartic proteinase group of enzymes. They appear to have arisen by duplication and expansion of a pepsin F-like gene soon after, or around the same time, that the Cetartiodactyla order arose (Fig. 1) (Hughes et al., 2000). They share many common features with other mammalian aspartic proteinases including a 9 exon and 8 intron gene organization and a bi-lobed structure that forms a cleft used for binding peptide substrates (Ganguly and Prasad, 2012). The name for these proteinases arises from the presence of two aspartic acids that participate directly in the catalytic mechanism. These aspartates are contained within each lobe of the protein and they reside alongside other highly conserved residues. The consensus sequence around each aspartate is hydrophobic-hydrophobic-Asp-Thr-Gly-Ser/Thr-Ser/Thr. These aspartates participate in peptide bond cleavage by orientating and stabilizing a water molecule that is complexed between them; it is the water molecule itself that acts as a nucleophile during the hydrolysis of the peptide bond of the bound substrate (Dunn, 2002). Most PAGs possess all the structural features of aspartic proteinases and proteolytic activity has been characterized for some of them (Telugu and Green, 2008; Telugu et al., 2010). However, there are a few that are highly likely to not have proteolytic activity because they either lack one of the catalytic aspartates or they contain atypical residues within the highly conserved sequences flanking them (Green et al., 2000; Xie et al., 1991). However, molecular modeling suggests that those PAGs predicted to lack proteolytic activity still possess the overall conformation of aspartic proteinases (Telugu and Green, 2008). In other words, any lack of activity does not seem to be associated with drastic alterations in the overall ability to bind peptide sequences via the binding cleft.

PAGs Are Restricted to the Cetartiodactyla Order

The PAG gene family is restricted to the Cetartiodactyla order. Animals within this order include swine, giraffes, cattle, bison, sheep, whales, and related species. When conducting a phylogenetic analysis of all known PAGs in public databases, there are currently over 250 total PAG genes present. Fig. 1 represents a simplified phylogenetic tree that illustrates the relationship between PAGs and other mammalian aspartic proteinases. Based on current genome sequencing results, PAG genes are most prevalent in ruminant species. In other species of the Cetartiodactyla order the number of PAG genes is smaller. For example, the number of total PAG genes present per species ranges from two genes represented in the genome builds of some whale species, to over thirty known PAG genes in many of the Bovidae (Telugu et al., 2009). It is notable that, when comparing across the different suborders (Suidae, Cetacea, Ruminantia), there is little indication that individual PAGs are conserved across the order. In other words, there are no obvious orthologs across the suborders, and all the PAGs represented by each suborder cluster together in phylogenetic analyses. It is not clear whether that pattern is due to expansion of PAGs in these species after their split from a common ancestor or due to homogenization of PAG genes in these suborders. There is also evidence that certain parts of these proteins (mainly surface loops) are evolving rapidly (Hughes et al., 2000).

Fig. 1 Evolutionary relationships among representative PAGs and mammalian aspartic proteinases. The PAGs belong to the aspartic proteinase family of enzymes. They seem to have arisen by an ancestral duplication of the pepsin F gene, which itself arose from an ancestral pepsin A gene. The PAGs have undergone extensive expansions and refinements within the suborders of the Cetartiodactyla. The phylogenetic tree displayed was inferred by using the Minimum Evolution method. Results from bootstrap tests (percentages from 1000 replicates) are shown next to the branches. The tree is drawn to scale, with branch lengths in the same units as those of the evolutionary distances which are in the units of the number of amino acid substitutions per site. The evolutionary analyses were conducted in MEGA7 (www.megasoftware.net).

The diversity in the number of PAG genes, their lack of orthology and/or their rapid evolution is suggestive that the functional role of PAGs is likely to differ across species within the suborders of the Cetartiodactyla. It is worth noting that all cetartiodactyls possess syn/epitheliochorial placentas that are adaptive forms that are distinct from the ancestral endotheliochorial or hemochorial forms (Wildman et al., 2006). Presumably, the PAGs are performing functions that are important for these unique placental forms. Speculations about those possibilities are elaborated upon below.

PAGs Are Expressed by the Placenta

The PAGs are products of trophoblast cells of the placenta (Fig. 2) (Wallace et al., 2015). The presence of PAGs in the placenta has been reported in pigs and several other cetartiodactyls. The expression of PAGs during development of the conceptus and placenta is best understood in cattle. In this species, the phylogenetically more ancient bovine PAGs (ones that represent the forms that arose earliest in the Cetartiodactyla order) are usually found to be expressed mainly by mononucleated trophoblasts although some are present in both mononucleated and GBCs (Fig. 2). The largest subgrouping of bovine PAGs have more recent origins and these are generally found to be restricted in their localization to GBCs (Green et al., 2000). These cells are particularly notable because of their capacity to fuse with nearby uterine epithelial cells to form a syncytial fetal-maternal cell type (Wooding, 1982). Upon fusion, the secretory granules within the giant trophoblasts move toward the basal side of the uterine epithelium. The contents of the secretory granules are then released via exocytosis toward the uterine connective tissue (Wooding, 1992). Since most PAGs are components of the GBCs granules, they ultimately are delivered to maternal tissues and can accumulate in maternal blood, milk and urine (Wallace et al., 2015). Most of what is understood about PAG localization and delivery to the maternal system is from examining placentomes (consisting of fetal cotyledons and maternal caruncles). Currently, little is known about PAG expression in inter-placentomal membranes.

Ruminant PAGs can Be Used to Evaluate Pregnancy Status

Bovine PAGs first become detectable in the maternal blood circulation around day 25 of pregnancy, which is soon after GBCs first form (Sasser et al., 1986; Wathes and Wooding, 1980; Zoli et al., 1992). Circulating concentrations rise steadily throughout pregnancy and peak around the time of parturition (Green et al., 2005; Sasser et al., 1986; Zoli et al., 1992). The appearance of these placental products in the maternal bloodstream of ruminants made these proteins useful markers for the detection of pregnancy in bred females. Indeed, multiple commercial assays have been developed and marketed for this purpose. In general these assays for bovine PAGs are able to detect pregnant animals at day 30 with 95% accuracy or greater. PAG assays represent an economical and efficient way to detect pregnancy relatively early in cattle as well as in sheep, deer and other ruminant ungulates (Huang et al., 1999; Melo De Sousa et al., 2003; Ranilla et al., 1994). In addition to PAGs' utility in detecting pregnancy, assessing PAG levels also

Fig. 2 Localization of PAGs at the placenta-uterine interface of pigs and cattle. Panels A, B and C are day 35 pig placenta. Panels A (100 $\times$) and B (400 $\times$) show immunohistochemical staining of trophoblasts obtained by using a porcine PAG2 antibody. Panel C (400 $\times$) is an unstained section stained with hematoxylin and eosin. The boxed area in panel A is the region shown in panel B. Panels D, E and F are bovine placental sections stained with different bovine PAG antibodies to illustrate the distinct expression patterns of PAGs in cattle and related ruminant ungulates. Panel D (200 $\times$) is a day 45 placental section stained with a bovine PAG2 antibody. This antibody stained both mononucleated and binucleated giant trophoblasts. Panel E (200 $\times$) is a day 75 placental section stained with a bovine PAG monoclonal antibody that reacts predominantly with PAG4 and PAG6. This antibody staining is restricted to binucleated giant trophoblasts. Panel F (200 $\times$) is a day 90 placental section stained with a bovine PAG8 antibody. This antibody stained mononucleated trophoblasts, but exhibited little or no staining of binucleated giant trophoblasts. FS, fetal stroma; US, uterine stroma; UE, uterine epithelium; T, trophoblast; arrowheads indicate binucleated trophoblast giant cells in bovine placentomes.

appears to be a way to predict future pregnancy loss in pregnant cattle. Several research teams have reported that circulating PAG levels are often reduced early in pregnancy in animals that will later experience fetal loss (Breukelman et al., 2012; Giordano et al., 2012; Humblot, 2001; Pohler et al., 2013; Pohler et al., 2016). Presumably, the lower circulating PAGs reflect a compromised placenta that is incapable of normal production of secretory proteins and that ultimately fails to adequately support the fetus (Pohler et al., 2013; Wallace et al., 2015). Over time, as these assays are perfected and more antibodies are developed to detect specific ruminant PAGs, they may provide improved diagnostic tools for assessing both the presence and likelihood of a successful outcome for a pregnancy.

Potential Functions of PAGs

The PAGs have been studied for more than three decades and there has been much speculation regarding the function of PAGs in pregnancy. The particular functions attributed to them generally hinges upon their presence at the placenta-uterine interface and their presence in the maternal milk and blood. The proposed functions have focused on putative roles in tissue remodeling, immunomodulation of the maternal immune system and/or luteotrophic actions on the ovary.

Many PAGs accumulate at the placenta-uterine interface. In pigs, which lack the fusogenic trophoblasts cells present in ruminants, the majority of PAGs that are secreted by trophoblasts do not enter the maternal circulation. Instead, they remain at the microvillar interface between the trophoblasts and the uterine epithelia (Majewska et al., 2006; Wooding et al., 2005). In cattle, those PAGs that are produced by mononucleated trophoblasts also appear to remain predominantly at the trophoblast-uterine interface (Wallace et al., 2015; Wooding et al., 2005). Wooding and colleagues suggested that catalytically active PAGs at the interface could have general or individualized capacity to proteolytically process other proteins present at that location, such as latent growth factors. Other possibilities for PAGs at the interface involve roles serving a structural purpose. It was speculated that PAGs may be acting as protein-binding proteins or as adhesion molecules that allow for docking of other proteins to the interface. The substrate binding cleft and/or the carbohydrate moieties displayed on their surface could permit interactions with other proteins (e.g. lectins) (Klisch et al., 2008; Wooding et al., 2005). If PAGs served as adhesion molecules, even enzymatically active PAGs could conceivably serve this purpose provided the pH at the microvillar junction is not so low as to stimulate their activity (most aspartic proteinases have greatest activity at low pH). Indeed, in this scenario, a pH drop, such as around parturition, could activate PAGs to promote cleavage of protein-protein connections between the placenta and uterus.

For those PAGs that are found in the maternal bloodstream, it was suggested that they may be modulating the maternal immune system. In regards to such an immunological role, PAGs are known to influence certain immune progenitor cell responses; conversely they may also aid in dampening the maternal immune response around the time of parturition (Dosogne et al., 2000; Hoebe et al., 1999; Hoebe et al., 2000). For example, some PAGs are able to bind to uterine serpins (Mathialagan and Hansen, 1996); increase the chemokine, GCP2, from endometrial cells (Austin et al., 1999); decrease hemopoietic cell proliferation, and modulate polymorphonuclear neutrophil leukocyte activity. Though many of the processes above are not directly related, PAGs may be able to modulate each process via similar mechanisms, including possible generation of ligands by proteolytic cleavage, interaction with PAG 'receptors' and by interacting with other proteins by their unusual glycosylation moieties (Klisch et al., 2008; Wallace et al., 2015; Wooding et al., 2005).

Another interesting possibility is that ruminant PAGs may play roles as luteotropic agents. They can elevate the luteotrophic prostaglandin, PGE₂, relative to that of the luteolytic prostaglandin PGF_{2α} (Weems et al., 2007; Weems et al., 2003; Weems et al., 1998). On the surface, this role is quite distinct from the functional hypotheses related to immunomodulation. However, it is worth noting that PGE₂ itself can also modulate immunological actions, which might be suggestive that the immune and luteo-protective actions attributed to PAGs may be due to overlapping signaling systems (Emond et al., 1998).

Summary

Pregnancy-Associated Glycoproteins (PAGs) are a gene family expressed by the placenta of species within the Cetartiodactyla order. They are members of the aspartic proteinase group of enzymes that arose from a series of gene duplication events. They are most closely related to pepsin F and pepsin A. The PAGs share the same bi-lobed structure that is typical of aspartic proteinases. However, some PAGs have amino acid substitutions in the active site of the molecule that may render them catalytically inactive. Genomic and cDNA sequencing has revealed the presence of numerous PAG members, especially within the Ruminantia suborder. In ruminants, their detection in the blood of pregnant females has revealed that they can serve as useful circulating markers of pregnancy.

The functions of PAGs are not known. However, they have been extensively studied and several models for PAG function have been proposed. Further research is needed to determine a specific role for these proteins, but as of yet, their transcriptional abundance and complexity suggests they are extremely important in the processes related to placentation in cetartiodactyls.

Adrenomedullin Signaling in Female Reproduction

Introduction

Peptide hormones are potent governors of reproductive processes with a versatile display of multi-factorial functions in a variety of tissues (Hinson et al., 2000). Peptides mirroring hormone-like properties retain the ability to pass through multiple cell membranes and easily collect in blood or lymph circulation awaiting transport to multiple tissues. One of these protein families, the calcitonin gene-related peptide (CGRP) family of conserved ligand peptides, was identified to exhibit a myriad of functions including the ability to control blood pressure and aid in neurotransmission (Hinson et al., 2000). This family is comprised of CGRP, calcitonin, amylin, adrenomedullin (ADM), and intermedin (IDM/ADM2). Although similar in structure, these peptides differ in functionality and receptor preference. CGRP, ADM and IMD ligands actively signal via a membrane-integrated G protein-coupled receptor called calcitonin receptor-like receptor or CLR, when the receptor is associated with one of three conjugate CLR interacting proteins, designated receptor activity-modifying proteins or RAMPs to elicit downstream functions (Gibbons et al., 2007). Thus, initiation of the CGRP signaling cascade is dependent on coordinate expression of the ligand, receptor, and receptor modifier in a particular target tissue. Activation of the CGRP ligand–CLR–RAMP complex elicits multiple second messenger signaling cascades including nitric oxide (NO) synthase, cAMP, and MAPK pathways (Gibbons et al., 2007), all of which are ubiquitous pathways, universally expressed in all tissues. These second messenger signaling pathways control cellular proliferation, differentiation, vasodilation, and metabolism of multiple tissues.

Within the CGRP family, ADM exhibits broad expression and function in a variety of tissues, with a strong role in cardiovascular and lymphatic vessel growth and homeostasis. ADM was identified in 1993 after Kitamura et al. identified a peptide exhibiting vasoactive properties expressed heavily in an adrenal pheochromocytoma, coining it “adrenomedullin” (Kitamura et al., 1993). Now, nearly a quarter of a century later, literature citations of ADM function range in the thousands, pertaining to multiple fields with reported expression in every organ system of the human body (Hinson et al., 2000). Due to its broad expression and function, it is of no surprise that ADM signaling is highly conserved across many species (Chang and Hsu, 2013). Besides being a potent vasodilator and important effector in lymphatic and cardiovascular development, ADM exhibits nontraditional functions as an anti-bacterial and antiinflammatory factor, combatting infections in the blood and surface of the skin, despite its short half-life of 23 min within the human body (Hinson et al., 2000). Additionally, ADM is highly expressed in the female reproductive tract, responsive to the ovarian steroid hormones, and has exhibited a strong role in the initiation and maintenance of a pregnancy (Lenhart and Caron, 2012). This article will discuss the role of ADM in multiple processes of pregnancy and in the initiation of or association with several reproductive-related diseases.

Of the CGRP ligands, ADM is the most widely studied in the field of female reproduction, exhibiting critical functions in the initiation, maintenance, and completion of pregnancy. Although expressed in the adrenal gland and particularly enriched in most vascular endothelial cells (Hinson et al., 2000), ADM also exhibits robust expression in female reproductive tissues including the uterine endometrium, ovary, oviduct, cervix, vagina, placenta, as well as fetal membranes including trophoblast cells (Lenhart and Caron, 2012). Furthermore, ADM is secreted by both maternal and fetal compartments of the placenta during pregnancy (Lenhart and Caron, 2012), resulting in approximately a 3–5 fold increase in serum ADM levels observed in pregnant women compared to nonpregnant women (Di Iorio et al., 1998). ADM is enriched in fetal-derived trophoblast cells in both human (6–10 weeks of pregnancy) and mouse (day 9.5) at the onset of pregnancy, with cognate receptors expressed on maternal tissues to elicit autocrine and paracrine control of pregnancy (Di Iorio et al., 1998, 2003). Expression of ADM alone is not sufficient to activate the ADM signaling pathway. ADM with its receptor, CLR, and receptor-modifying protein, RAMP2 or RAMP3, are required for downstream signaling (Gibbons et al., 2007). Indeed, ADM and its signaling components, CLR and RAMP2/3, are all responsive to the presence of the ovarian steroid hormones and are present in the uterus and uterine vasculature (Chang and Hsu, 2013). Thus, coordinate expression within maternal and fetal tissues of ADM, CLR, and RAMPs is required for successful ADM signaling during pregnancy.

Aberrant expression of ADM in the fetal or maternal tissues is often indicative of diseased conditions such as fetal growth restriction (FGR), preeclampsia, and other reproductive-associated diseases (Lenhart and Caron, 2012). Although a working foundational knowledge of ADM signaling exists, there is still a lack of understanding regarding the mechanisms following local ADM signaling activation in the uterus and placenta. Further investigation of ADM signaling in the reproductive tract is required to understand this complex signaling pathway. In the following paragraphs of this article, the known and potential roles of ADM in the female reproductive tract throughout every step of pregnancy will be explored. Finally, the involvement of ADM signaling in the provocation of female reproductive-associated disease and the potential for clinical therapeutic use will be described.

Adrenomedullin Function in Pregnancy

Ovulation

Upon prompting from the hypothalamic–pituitary axis, the ovaries control the appropriate secretion of the steroid hormones and at the onset of pregnancy, govern the timely release of the developed oocyte into the fallopian tube (Wang and Dey, 2006). During

menses, circulating ADM protein increases during the follicular phase of ovulation, while decreasing at the luteal phase, coinciding with the increase in ovulatory estrogen production (Di Iorio et al., 2003). Additionally, circulating ADM levels increase dramatically with the luteinizing hormone surge, responsible for ovulation and release of the developing oocyte (Di Iorio et al., 2003). Indeed, ADM levels are increased in ovarian follicular fluid extracts, providing a potential role for ADM in the maturation and release of a developed egg (Di Iorio et al., 2003, Chang and Hsu, 2013). Experiments in the rat have also identified a potential role of ADM in the promotion of progesterone ligand, the ovarian hormone required for pregnancy, in the ovarian granulosa cells via cAMP second messenger signaling (Di Iorio et al., 2003). Therefore, ADM is sensitive to ovulatory estrogen secretions and may potentiate oocyte maturation and aid in the production of progesterone ligand within the ovary.

Conception and Embryo Transport

At the onset of human conception, an egg is released from the ovary and travels down the fallopian tube at which it is intercepted by sperm. The fallopian tube is not just a means of delivery for the embryo to the uterus, but functions as a perfect environment for conception to occur and for the embryo to appropriately advance in development (Ezzati et al., 2014). Ciliated cells lining the fallopian tube beat the embryo in a timely manner to the receptive uterus. The uterus is receptive to the implanting embryo for a narrow time frame, coined “the window of receptivity” (Wang and Dey, 2006). This window occurs in both mice, at day 4 of pregnancy, and in women, at day 9 of pregnancy. It is during this unique time in which the uterus is prepared to receive the developed embryo from the fallopian tube (Wang and Dey, 2006). Late arrival of the embryo results in embryo destruction, while early embryos await the receptive time point. ADM is expressed within the endothelial cells lining the murine oviduct and human fallopian tube (Chang and Hsu, 2013). Additionally, ADM promotes the cilia beat frequency resulting in timely delivery of the fertilized embryo to the receptive uterus in the rat (Liao et al., 2011). The presence of sperm within the fallopian tube also enhances ADM levels, resulting in increased ciliary beating (Fazeli et al., 2004). Thus, ADM not only regulates ovulation and conception, but also controls the duration of time the embryo stays within the fallopian tube, resulting in a well-timed delivery of the developed embryo to the uterus.

Embryo Implantation

The establishment of a receptive uterine state is a complex process involving molecular crosstalk between both the uterine epithelial and stromal compartments. The ovarian steroid hormones govern this process of early pregnancy initiation and maintenance (Wang and Dey, 2006). Interestingly, ADM exhibits estrogen response elements in its promoter region (Watanabe et al., 2006) and is coordinately upregulated in pregnancy or by administration of a progestin (Hinson et al., 2000). Thus, ADM is hormonally responsive and involved in multiple processes of pregnancy. Upon expression of estrogen, the uterine epithelium proliferates and forms endometrial glands responsible for secreting critical growth factors required for embryo implantation (Wang and Dey, 2006). As early pregnancy progresses, the uterine epithelium is exposed to a predominance of progesterone ligand resulting in multiple morphological changes to the epithelial cells, allowing for reception of the embryo (Wang and Dey, 2006). Epithelial cells change in polarity and form bleb-like structures called uterine pinopodes on their outer surface facing the uterine lumen as potential “homing beacons” for implanting embryos (Quinn and Casper, 2009). These pinopodes are hypothesized to express adhesion molecules and aid in the attachment and integration of the implanting embryo on the epithelial surface (Quinn and Casper, 2009). Concurrently, the ADM signaling components, CLR, RAMP2, and RAMP3 exhibit expression in the luminal epithelium just prior to the time of implantation (Li et al., 2008). Single allelic ablation of ADM resulted in reduced litter size and a reduction of pinopode number, confirming its integral role in the attachment and implantation of embryos (Li et al., 2006). Indeed, increased expression of ADM restored litter size in the murine model (Li et al., 2013). Furthermore, exogenous administration of ADM to pseudopregnant dams, (female mice mated to vasectomized mice), receiving blastocyst transfers, caused a higher embryo receptivity rate and improved embryo spacing compared to normal blastocyst transfers in wild type mice (Matson et al., 2017). Thus, ADM promotes embryo reception rate and implantation spacing, making it a strong therapeutic candidate for in vitro fertilization. ADM also promotes water retention within the stroma at the time of implantation (Matson et al., 2017), which may aid in ionic balance and fluid homeostasis within the inter-luminal space, factors speculated to be critical for embryo receptivity (Liu et al., 2014). Additionally, a surge of estrogen initiates the time of implantation, coordinately promoting ADM expression and RAMP3 expression in the uterine endometrium, the stroma, and the blastocyst at the time of implantation (Lenhart and Caron, 2012). This surge likely supports the implantation of the embryo while simultaneously preparing the stroma for increased proliferation and angiogenesis. Thus, ADM regulates pinopode formation, embryo receptivity rate and spacing, and ionic balance responsible for the preparation of the receptive uterine epithelium for the attaching embryo. Further studies are required to understand the extensive functions of ADM at the implantation surface, many of which are unknown.

Decidualization

After the embryo implants into the uterine epithelium, the stromal decidual reaction begins, an extensive process also known as decidualization. Decidualization encompasses a wave of differentiation and proliferation of the stromal cells into epithelial-like cells, with a marked response in angiogenesis, important for the appropriate growth and support of the embryo. Although ADM is expressed in the epithelial uterine compartment and in the postimplantation decidual stromal cells surrounding the attached

embryo (Li et al., 2006), there is limited knowledge regarding the role of ADM in the decidualization process. Based on its extensive expression pattern and known functions, ADM likely enhances the vascular permeability and angiogenesis surrounding the developing embryo (Yallampalli et al., 2014). Therefore, ADM exhibits a potential role in the promotion of blood flow and delivery of necessary nutrients before the development of the placenta.

Placentation

After implantation and decidualization, cells from the fetal trophoblast migrate and invade through the maternal tissue in order to establish a vascular conduit between fetal and maternal networks (Lenhart and Caron, 2012). These invaded trophoblast cells recruit specialized immune cells known as uterine natural killer (uNK) cells to the site of placental formation, the maternal spiral arteries (Smith et al., 2009). The recruitment of uNK cells is strongly dependent on the level of ADM secretion by the trophoblast cells (Li et al., 2006, 2013). Within genetically engineered mouse models, increased expression of ADM increases the uNK cell population, while heterozygous ablation of ADM results in decreased recruitment of uNK cells (Li et al., 2006, 2013). The presence of uNK cells is necessary for the induction of matrix metalloproteinases (MMPs) and other growth factors, such as vascular endothelial growth factor, causing the apoptosis of vascular smooth muscle cells and eventual remodeling of the maternal spiral arteries (Lenhart and Caron, 2012). After invasion of the trophoblast cells, expression of ADM, and recruitment of uNK cells, the maternal spiral arteries are remodeled from low-capacitance, high pressure vessels into high-capacitance, low pressure vessels allowing for the maximum exchange of nutrients between mother and baby (Lenhart and Caron, 2012). Since the placenta is not autonomously innervated, vasoactive agents and downstream endothelial cell remodelers are required for this structural remodeling of the spiral arteries and development of the placenta as well as the control of systemic blood pressure and vascular flow (Di Iorio et al., 2003). This is performed by activation of second messenger signaling cascades downstream of ADM such as the NO pathway, resulting in low vascular resistance, and the cAMP pathway, allowing for the rebuilding of vascular walls (Di Iorio et al., 2003). Therefore, invading fetal trophoblast cells initiate the remodeling of the maternal spiral arteries by the recruitment of specialized immune cells and activation of second messenger signaling via ADM. These immune cells further recruit vasoactive growth factors and remodeling enzymes, resulting in the formation of the placenta and efficient exchange of nutrients, gasses, and waste between mother and baby.

It is of utmost importance that the placental maternal arteries be remodeled into large, high-capacitance vessels, as inappropriate spiral artery remodeling can result in systemic maternal hypertension and risk for FGR (Chaiworapongsa et al., 2014). FGR is a serious condition for the infant that can lead to multiple developmental abnormalities (Sharma et al., 2016). Upon ablation of a single allele of ADM within mice, pregnant females exhibit a reduced litter size due to FGR (Li et al., 2006). Placentas from embryos exhibiting FGR had shallow placentas with fragile maternal and fetal neighboring components and a dysregulated decidual boundary (Li et al., 2006), defects often observed in women with preeclampsia, a severe hypertensive pregnancy disorder. Additionally, genetic rescue of ADM expression crossed onto the ADM ablated mice rescued the FGR and reduction in litter size (Li et al., 2013). Thus, ADM expression is necessary for placental development resulting in the appropriate exchange of gasses and nutrients between the fetal and maternal tissues. Additional investigation is required to identify the factors affecting ADM signaling and how these complex mechanisms communicate leading to the successful establishment of a healthy placenta.

Parturition

After completion of placentation, the fetus grows until the time of delivery or parturition. Parturition, much like many processes of pregnancy, is regulated by a myriad of factors ultimately resulting in contraction of the uterine muscles or myometrium and ripening of the cervical tissue (Mendelson, 2009). Multiple hormones, cytokines, growth factors, and inflammatory molecules are important for preparing the uterine myometrium for parturition (Mendelson, 2009, Di Iorio et al., 2003). Before the onset of muscle contraction, inflammatory molecules and cytokines are recruited to the uterus, causing the upregulation of the NFκB pathway and inhibition of the progesterone signaling pathway (Mendelson, 2009). Through this synergistic action, the myometrium is prepared for physical contraction, yet dependent on intracellular stores of Ca^{+2} ions. ADM is present within the smooth muscle cells of the uterus with increased expression in pregnant uterus versus nonpregnant uterus (Di Iorio et al., 2003). The presence of ADM in the uterus is hypothesized to quiet the uterine tissue through elevated cAMP signaling (Di Iorio et al., 2003). However, ADM may also regulate uterine quiescence via other contractile factors and additional second messenger signaling cascades. Indeed, ADM was identified to suppress uterine myometrial contractility in a concentration-dependent manner using rat tissue contractility studies (Di Iorio et al., 2003). Despite this convincing evidence, ADM is consistently upregulated in amniotic fluid from women undergoing preterm birth and in plasma prior to cervical ripening at the onset of labor (Di Iorio et al., 2003). Although expression of ADM at the time of labor is contrary to the quiescent hypothesis, the increased expression may be a direct result of the surge in immune cell population present at the time of labor. Because ADM functions as a circulating antiinflammatory compound, it is induced in the presence of diseased or inflamed states, providing a potential explanation for the sharp increase in ADM before the initiation of labor. Additionally, ADM upregulation was proposed to initiate NO, relaxin, and prostaglandin signaling cascades required at the time of cervical ripening (Di Iorio et al., 2003). Therefore, ADM signaling functions as a uterine relaxant during uterine quiescence, but can be upregulated at the onset of labor in the presence of increased immune cells or at the start of cervical ripening. In conclusion, the involvement of ADM signaling in the maintaining of a pregnancy and initiation of parturition is complex and requires further investigation to determine the downstream signaling mechanisms affecting uterine contraction.

Adrenomedullin in Reproductive-Associated Disease

As ADM is an important regulator of the initiation and maintenance of pregnancy, it is of no surprise that modifications in ADM expression can result in severe consequences to the female reproductive tract and future fecundity. Due to known ADM functions, reduction in ADM expression is indicative of decreased second messenger signaling via cAMP, NO, and MAPK pathways which can have devastating effects on the progression of pregnancy. However, increased circulating amounts of ADM can describe a variety of different situations. High circulating or local ADM expression may be helpful in some reproductive situations, yet it also exhibits upregulation to balance a diseased state, as is observed in patients with sepsis (Lenhart and Caron, 2012). Thus, the function of ADM signaling in reproductive-associated disease is complex and the current understanding of its role in the maintaining of reproductive health will be outlined in the following paragraphs.

Recurrent Implantation Failure

For women deemed infertile, defined as a failure to become pregnant after 1 year, various treatments can be administered to promote pregnancy. These treatments can vary from fertility drugs, hormone supplements, and potentially in vitro fertilization (IVF), which currently has a success rate of 50% (Timeva et al., 2014). Women who undergo multiple rounds of IVF and still fail to become pregnant are diagnosed with recurrent implantation failure (RIF). Women with RIF exhibit much difficulty becoming pregnant, often requiring highly technical variations of IVF and/or strong implantation therapeutic drugs (Timeva et al., 2014). Recently, an IVF clinical trial consisting of infertile women with and without RIF was performed to correlate the number of pinopodes with embryo receptivity success rate (Qiong et al., 2017). They were able to discern a positive correlation between pinopode number and successful embryo implantation. Furthermore, women with RIF exhibited poor receptivity rates with severely low pinopode numbers (Qiong et al., 2017). Thus, increased pinopode number is likely a valuable indicator of successful implantation. Interestingly, genetic reduction of ADM results in fewer pinopodes (Li et al., 2008) and treatment of wild type mice with ADM at the time of implantation dramatically increases pinopode formation (Matson et al., 2017). Additionally, exogenous administration of ADM with developed blastocysts in wild type mice prepared for pregnancy dramatically enhanced embryo receptivity success. Furthermore, the implantation spacing of the embryos was improved compared to vehicle treated wild type mice (Matson et al., 2017). Thus, ADM promotes the formation of pinopodes and enhances implantation success and embryo spacing. Therefore, ADM could be used as a powerful therapeutic intervention for women suffering from RIF.

Tubal Ectopic Pregnancy

Improper ciliary beating or oviductal muscle contraction can result in a rare pregnancy complication, known as tubal ectopic pregnancy (Horne and Critchley, 2012). In this condition, the embryo fails to travel down the fallopian tube in a timely manner and implants into the fallopian tube instead of the uterus. This aberrant implantation can lead to rupture and massive internal bleeding usually requiring surgery (Horne and Critchley, 2012). If not immediately remedied, ectopic pregnancies can lead to severe internal bleeding that can be deadly. As described previously, ADM is expressed in the endothelial cells lining the fallopian tube and is known to promote ciliary beat frequency for embryo delivery. In a recent study, the role of ADM in the formation of tubal ectopic pregnancies was examined (Liao et al., 2012). Interestingly, ADM was decreased in oviductal tissue obtained from human patients with tubal ectopic pregnancies. Although further investigation is required to understand the full scope of ADM function in the oviduct, these studies provide a potential mechanism for the effect of decreased ciliary beat by insufficient ADM in the instigation of tubal pregnancy.

Endometriosis

Endometriosis, or the presence of the endometrium outside of the uterus, occurs in up to 10% of the US population (Kim et al., 2013). Endometriotic lesions are hypothesized to generate from retrograde menstrual flow out of the fallopian tube into the surrounding peritoneal cavity (Kim et al., 2013). These uterine tissues can attach to ovaries or other interior organs and as uterine tissue, are responsive to the systemic expression of the ovarian steroid hormones, especially estrogen secretion (Kim et al., 2013). The endometriotic lesions often develop resistance to progesterone, making them difficult to treat, resulting in further growth and discomfort (Kim et al., 2013). The role of ADM in endometriosis is relatively unknown with few papers commenting on ADM expression or function in endometriosis. The limited papers from endometriotic patient samples report ADM expression is increased in follicular fluid after a round of IVF (Singh et al., 2016) and also upregulated in peripheral leukocytes from blood samples (Gentilini et al., 2011). Being estrogen responsive, endometriotic lesions exhibit proinflammatory and pro-proliferative qualities. Thus, ADM is speculated to be increased within local and systemic environments in these patients for a variety of reasons: 1.) ADM is upregulated in the presence of increased estrogen signaling, 2.) ADM increases upon abundance of circulating inflammatory markers to quiet the inflammation, 3.) ADM is often an upstream effector of pro-proliferative and proangiogenic pathways observed in growing endometriotic lesions. Therefore, besides being upregulated in blood samples, ADM is also likely increased in endometriotic tissues. ADM may exhibit a significant role in the exacerbation of this reproductive-associated disease, yet further inquiry is required to assess its function in the formation and maintenance of endometriotic lesions.

Preeclampsia

The appropriate formation of the placenta is critical for the progression of pregnancy and nourishment of the growing fetus. Abnormal placentation can result in fetal and maternal complications that can be lethal or can lead to future cardiovascular disease. Since nutrient exchange occurs at the placenta, aberrant placental development is integrally linked with FGR as it is often inevitable for the fetus to obtain the nutrients required for appropriate development. Currently preeclampsia is responsible for over 50,000 maternal deaths and FGR accounts for around 50% of stillbirths worldwide per year (Sibley, 2017). Thus, understanding the mechanisms that lead to improper formation of the placenta is absolutely critical for the treatment of this disease.

As mentioned previously, ADM is secreted by both the fetal and maternal tissues, promoting the efficient invasion of the fetal trophoblasts through the maternal tissue and initiating the recruitment of the uNK cells (Lenhart and Caron, 2012). The uNK cells recruit growth factors and cytokines responsible for the efficient remodeling of the spiral arteries into high-capacitance vessels for maximum transport of nutrients to the fetus (Lenhart and Caron, 2012). Ablation of ADM in a mouse model causes preeclamptic-like conditions including reduced litter number due to FGR from abnormal placental development (Li et al., 2006). These defects are rescued by inducing a genetic increase of ADM in the entire mouse (Li et al., 2013), providing strong evidence for the role of ADM in placental formation and protection of preeclampsia. Similarly, infusion of ADM in a hypertensive pregnant rat model reduced hypertension and fetal loss without posing negative effects on systemic blood pressure or fetal survival in wildtype animals (Di Iorio et al., 2003). However, confirming this protective relationship in preeclamptic women has proven challenging. Levels of circulating ADM are often difficult to detect due to its short half-life and physical characteristics and binding capabilities making it difficult to assay (Lenhart and Caron, 2012). However, Matson et al. described a new assay to measure the cleaved propeptide portion of ADM, which is stoichiometrically equivalent to the amount of ADM peptide in circulating plasma (Matson et al., 2014). Not surprisingly, the propeptide of ADM is strongly decreased in circulating plasma from women with severe preeclampsia compared to normotensive women (Matson et al., 2014). Thus, increased ADM levels strongly correlate with a normotensive pregnancy. With this known, further investigation is needed to identify new therapies targeting the upregulation of ADM during early pregnancy to ensure appropriate placental development.

Endometrial Cancer

Although hormone responsive and often successfully treated by therapy or surgery, endometrial cancer is the most common reproductive-associated disease in the United States (Kim et al., 2013). There are two major types of endometrial cancer (Kim et al., 2013). The first is estrogen dependent and is often a low-grade cancer with a favorable prognosis, often resulting from chronic estrogen supplements without counterbalancing progesterone supplementation (Kim et al., 2013). The second type is a rare, estrogen independent, high-grade cancer, with a poor prognosis. Within endometrial adenocarcinoma cells, ADM treatment caused hypoxia-induced apoptotic resistance by promoting expression of the oncogene and apoptosis protector, BCL-2 (Oehler et al., 2001). Other studies have identified ADM acting synergistically with VEGF to promote angiogenesis and proliferation in human endometrial cancer biopsies and endometrial adenocarcinoma cell lines (Evans et al., 2012). This is unsurprising as ADM is often induced by hypoxic conditions to promote vasculogenesis (Lenhart and Caron, 2012). In addition to furthering endothelial cell growth in the blood and lymph vasculature, ADM also promotes cellular permeability which may result in metastasis (Karpnich et al., 2011). Thus, ADM signaling may worsen endometrial cancer and metastasis. Utilization of a combined therapy to suppress ADM and estrogen signaling pathways may prove beneficial in the treatment of endometrial cancer.

ADM As a Therapy and Biomarker in Human Reproductive-Associated Disease

The structure and function of ADM as a circulating peptide in all vasculature validate ADM as an obligatory therapeutic target for a variety of human diseases. As a stabilizer for inflammatory disease states and a natural antibiotic, ADM is a promising candidate as an antiinflammatory drug for diseases such as sepsis and colitis (Gibbons et al., 2007). However, since ADM is a potent vasodilator, there can be severe risks systemically with elevated circulating ADM levels. As an alternative, a modified form of ADM or locally administered upstream activator of ADM may be used to circumvent the vasodilating properties and short half-life of the original compound. Recently, ADM has been tested in clinical trials for treatment of inflammatory bowel disease (Kato and Kitamura, 2015). In addition, there are currently high expectations for clinical trial testing of ADM administration during the IVF procedure to enhance embryo receptivity rates. By administering ADM with IVF to women suffering from RIF, the embryo implantation success rates may be significantly improved (Matson et al., 2017). Thus, despite the side effect of systemic vasodilation, ADM is still a promising candidate for IVF treatment and the prevention of inflammatory disease and infection.

Preeclampsia is a devastating hypertensive pregnancy disorder resulting in rampant fetal and maternal death worldwide. Currently, there is no cure for this disease, nor is there an easy means of detecting preeclamptic patients early. Recently, an assay was utilized to measure total circulating ADM plasma levels by measuring the stoichiometrically similar cleaved propeptide portion of ADM (Matson et al., 2014). The physical characteristics of ADM provide a difficult means to attain an accurate measurement of circulating ADM. Measuring the propeptide form circumvents these obstacles, resulting in an accurate measurement of circulating ADM. By measuring propeptide levels in circulating plasma from normotensive and severely preeclamptic patients, propeptide levels were robustly decreased in severe preeclamptic patients compared to normotensive patients (Matson et al., 2014). Therefore,

if implemented early, propeptide levels could be an accurate predictor of risk for preeclampsia. Currently few assays exist to diagnose preeclampsia and these methods are late and not helpful for women suffering from this disease. Thus, further investigation is required to identify and implement new biomarkers for early diagnosis of preeclampsia.

Conclusion

ADM is a robust circulating peptide hormone with multiple functions in cardiovascular and lymphatic development and reproductive processes. ADM is a model example of the functional diversity represented by peptide hormone families, especially the CGRP family. The knowledge base of ADM and especially its function in pregnancy has grown exponentially in the last 10 years. However, due to the extreme complexity of ADM signaling in the promotion of embryo delivery and attachment, the vascularization and restructuring of the maternal decidua and spiral arteries, and the control of fine-tuned signaling mechanisms at the onset of labor, further understanding is still needed. Deepened understanding of the pathways that communicate with the ADM signaling pathway will benefit the development of extensive therapies to treat reproductive-associated disease as well as establish new biomarkers for early diagnosis of these devastating diseases. Finally, in the expectant future, ADM or modified versions of ADM will be implemented more commonly as a therapeutic in the treatment of inflammatory disease or infection and in the enhancement of IVF treatment.

Placental Angiogenesis

Lawrence P Reynolds, Anna T Grazul-Bilska, and Pawel P Borowicz, North Dakota State University, Fargo, ND, United States

© 2018 Elsevier Inc. All rights reserved.

Glossary

Angiogenesis The formation of a new vascular bed from a pre-existing one.

Capillary The smallest blood vessel (approximately 5 μm in diameter) consisting of an inner layer of flattened (squamous) epithelial cells, called endothelial cells, and an outer layer of vascular smooth muscle-like cells, called pericytes. The capillaries are the site of exchange of nutrients, respiratory gases, and metabolic wastes between the tissues and circulatory system, whereas the pericytes are thought to regulate endothelial function.

Circulatory system The system that distributes blood to the body's organs and tissues and returns the blood and tissue fluid to the heart—includes the heart, arteries, veins and lymphatics—also called the vascular system.

Compromised pregnancy Any pregnancy in which fetal or placental growth, or both, are abnormal.

Endothelial cells The specialized, flattened (squamous) epithelial cells that line, or form the inner layer, of the entire circulatory system including the heart (where they are called endocardial cells, or the cells making up the endocardium).

Endothelium The inner layer of all blood vessels, made up of endothelial cells. The endothelium comprises a single, complete layer of cells.

Metabolic wastes By-products of metabolism which cannot be used by the body or are even toxic and must therefore be eliminated—these include metabolic water (which is an end-product of aerobic metabolism), carbon dioxide, and ammonia.

Metabolism The processes involved in supply of energy to support cellular activities including accumulation (accretion, anabolism) of materials and destruction (catabolism) of materials including the processes involved in detoxification and excretion. Metabolism can be oxidative (requiring oxygen, also called aerobic) or anaerobic (oxygen independent).

Nutrients A nutritive, nutritious substance required to remain healthy—usually divided into macronutrients (nutrients required in relatively large quantities), which includes carbohydrates, proteins, and fats, and micronutrients (nutrients required in relatively small quantities), which includes minerals (e.g., calcium, potassium, iron, selenium, zinc, etc.) and vitamins.

Pericytes Vascular smooth muscle-like cells that are one of the cell types making up and critical to normal function of capillaries—these exist outside of the endothelium.

Respiratory gases Gases (oxygen, carbon dioxide, nitric oxide) involved in respiration, which includes the processes involved in supplying oxygen to the tissues and cells to support metabolism and removing carbon dioxide which is a product of metabolism.

Vascular bed Also called the microcirculation—composed of arterioles (the smallest arteries), capillaries, and venules (the smallest veins) within a tissue (such as the placenta). It provides for exchange of nutrients, respiratory gases (e.g., O_2 and CO_2), and metabolic wastes (e.g., urea) between the tissues and the circulatory system.

Vasculogenesis The de novo formation of a new vascular bed in situ, as happens during early embryogenesis and placentation.

Introduction

Growth of vascular beds, which includes capillaries, venues and arterioles, is termed angiogenesis, is essential for growth and development of tissues because the capillaries are the site of exchange of nutrients, respiratory gases, and metabolic wastes between the tissues and circulatory system. Angiogenesis begins with formation of new capillaries and culminates in a new microcirculatory bed. As shown in **Fig. 1**, the initial component of angiogenesis, capillary proliferation, consists of:

1. Production of proteases by the existing capillary (endothelial) cells, which results in breakdown of their basement membrane (basal lamina).
2. Once the basement membrane is broken down, the endothelial cells of the existing capillaries proliferate and then migrate towards the angiogenic stimulus, which might be low tissue oxygen (hypoxia) or an angiogenic growth factor.
3. The new vascular tubes begin to form a lumen so that blood can begin circulating through them.
4. The newly formed capillaries form their own basement membrane and recruit vascular smooth muscle-like cells, pericytes, which are the final steps in maturation of the newly formed capillary bed.

The term angiogenesis, which is derived from Greek *angei*, vessel, and *gignesthai*, to be born, was first coined in 1935 by Arthur T. Hertig in his study of blood vessel development in the early placenta of humans and macaques ([Hertig, 1935](#)). This is appropriate, as angiogenesis not only supports growth and development of the placenta, but also, as we will discuss below, is critical for the large increase in placental blood flow that occurs during pregnancy and provides metabolic support to the growing fetus.

Fig. 1 The process of angiogenesis. In response to an angiogenic stimulus and secretion of angiogenic factors (AFs): (1) the endothelial cells (green ovals) of the existing capillary vessel produce and release proteases that dissolve the existing basement membrane (red line); (2) once the basement membrane is broken down the endothelial cells of the existing capillaries proliferate and then migrate towards the angiogenic stimulus—the direction of migration is based on the “angiogenic gradient”; (3) the new endothelial tubes begin to form a lumen so that blood can begin circulating through them; and (4) the newly formed capillaries form their own basement membrane and also recruit vascular smooth muscle-like cells, pericytes (red ovals), which are the final steps in maturation of the newly formed capillary bed.

Because angiogenesis supports tissue growth, it is seen primarily in tissues during pre- and post-natal development, whereas the vascular beds of adults are quite stable. In fact, when it does occur in adults, angiogenesis is often associated with pathological conditions, such as tumors, retinopathies, hemangiomas, etc. The exception is that angiogenesis occurs in adults during wound healing, and also in tissues that undergo cycles of growth and regression including those of the reproductive system—for example, ovaries, uterus, testis, and placenta.

The vascular bed, also called the microcirculation, is composed of arterioles (the smallest arteries), capillaries, and venules (the smallest veins) and is located within the tissue itself. Because the vascular bed provides for exchange of nutrients, respiratory gases (e.g., O_2 and CO_2), and metabolic wastes (e.g., urea) between the tissues and the circulatory system, its size is proportional to the metabolic requirements of the tissue. For example, as the metabolic rate of the tissue increases, so does the density of capillaries within that tissue. Conversely, as tissue oxygen levels increase, angiogenesis decreases, and vice versa. That is, low tissue oxygen, which is not sufficient to support the metabolic needs of the tissue, not only is a signal for dilation of blood vessels (and hence increased blood flow) but also is a primary “signal” for increased capillary growth, or angiogenesis (Fig. 1).

Placental Angiogenesis and Blood Flow During Normal Pregnancy

Both uterine blood flow, which supplies the entire gravid uterus (the uterine tissue, the placenta, and the fetus), and umbilical blood flow, which supplies the fetus and the fetal part of the placenta, increase dramatically during normal pregnancy. During the last 40% of pregnancy in humans, for example, uterine blood flow increases by 2.5-fold and umbilical blood flow by 5.5-fold (Fig. 2). Similarly, during the last 50% of pregnancy in cattle and sheep, uterine blood flow increases by 3.0- to 4.5-fold, whereas umbilical blood flow increases by 19-fold (Fig. 2). Conversely, the extraction rate per unit of blood, which is also known as the arterial-venous difference, increases less than 1-fold over the same period. Thus, for example, the 10- to 20-fold increase in oxygen (O_2) consumption by the gravid uterus and fetus (Fig. 3A) can be accounted for primarily by the increases in uterine and umbilical blood flows (Figs. 2 and 3B). This is also true for other nutrients including glucose and amino acids. The increase in umbilical blood flow keeps pace with fetal growth, such that umbilical blood flow and O_2 consumption per unit of fetal weight remain relatively constant both across stage of gestation within a species and between species.

Because capillary beds are arranged as a parallel rather than a serial system, blood flow to any tissue is proportional to the total cross sectional area of the capillary bed, which dictates resistance to flow. Thus, to a large extent, the large increase in blood flow to the placenta (i.e., uterine and umbilical blood flows) depends on growth of the placental vascular beds—that is, on placental angiogenesis.

To examine the pattern of placental angiogenesis, we chose to use sheep as a model, because the type of placenta, called cotyledonary, allowed us to examine both uterine, or maternal placental (also termed endometrial or caruncular), and fetal placental (also termed chorioallantoic or cotyledonary) angiogenesis. We accomplished this by cannulating the uterine artery or the umbilical artery and then perfusing the maternal or fetal placental vascular beds with a fixative before embedding the placental tissues in paraffin and sectioning by microtomy. Initially we stained the tissue sections using a histochemical method, called periodic acid-Schiff's reagent, that stained the capillary basement membranes and then quantified vascular development via image analysis. We subsequently have used more sophisticated methods, including immunofluorescence and confocal microscopy, to examine the pattern of placental angiogenesis.

Fig. 2 Fold increase in uterine and umbilical blood flows during the last 0.4–0.5 (40%–50%) of pregnancy in sheep, cow, and human. Data are expressed as fold-increase compared with the level at 50% or 60% of pregnancy. Data taken from Meschia, G. (1983). Circulation to female reproductive organs. In Shepherd, J.T. and Abboud, F.M. (eds.) *Handbook of physiology*, Sec 2, Vol III, Part 1. pp 241–69. Bethesda, MD: American Physiological Society; Rosenfeld, C.R., Morriss, F.H., Makowski, E.L., Meschia, G. and Battaglia, F.C. (1974). Circulatory changes in the reproductive tissues of ewes during pregnancy. *Gynecological Investigation* 5, 252–268; Reynolds, L.P., Ferrell, C.L., Robertson, D.A. and Ford S.P. (1986). Metabolism of the gravid uterus, foetus and uteroplacenta at several stages of gestation in cows. *Journal of Agricultural Science, Cambridge* 106, 437–444 and Konje, J.C., Howarth, E.S., Kaufmann, P. and Taylor, D.J. (2003) Longitudinal quantification of uterine artery blood volume flow changes during gestation in pregnancies complicated by intrauterine growth restriction. *British Journal of Obstetrics and Gynaecology* 110, 301–305.

What we found was that although the maternal placental capillary bed grows and develops extensively throughout pregnancy, growth of the fetal placental capillary bed is even more extensive. This mirrors the larger percentage increase in umbilical compared with uterine blood flow depicted in **Fig. 2**. Moreover, in the sheep, the pattern of vascular growth differs dramatically between the maternal and fetal placenta. In the maternal placenta, capillaries become much larger in diameter as gestation progresses, but the increase in capillary density (whether one measures area, number, or surface density—that is, capillary area, number, or surface area per unit of tissue volume) is only modest, on the order of 1.5- to 3-fold (**Fig. 4A and B**). Conversely, in the fetal placenta the capillaries become smaller as gestation progresses, but the capillary density increases from 6- to 12-fold for capillary area, number, and surface area (**Fig. 4A and B**). We have verified this difference in the pattern of capillary growth using a method called ‘vascular casting’ and scanning electron microscopy (**Fig. 4B**). This pattern of capillary growth would dictate a low-resistance, low-velocity flow of blood through the maternal placental tissue, which we have termed ‘irrigation’ flow, and is ideal for nutrient delivery. On the other hand, the pattern of capillary growth of the fetal placental vascular bed results in a large surface area, which is optimal for nutrient transport.

Is this pattern of placental vascular growth unique to ruminants like sheep, or is it similar among mammals? The mouse placenta develops a very similar vascular architecture (Adamson et al., 2002), and the human placenta is probably the ultimate irrigation flow system, as in primates the fetal membranes digest away a large part of the uterine wall, such that the fetal villi, or cotyledons, are suspended in a pool of slowly percolating maternal blood (**Fig. 5**).

Because angiogenesis is also critical to support growth of tumors, the factors that are involved in the angiogenic process are well studied. Just as for tumors and other tissues, it appears that placental angiogenesis is dependent on production of angiogenic factors by the placenta itself, including vascular endothelial growth factor (VEGF) and nitric oxide (NO) (**Fig. 6**). Other growth factors and cytokines, such as the chemokine family, also may be involved. The involvement of nitric oxide is important, as it also serves as a major vasodilator, and therefore may coordinate placental vascular growth with placental blood flow to meet the metabolic demands of fetal and placental growth.

Placental Angiogenesis and Blood Flow During Compromised Pregnancy

The sheep is a widely used model for study of pregnancy complications for numerous reasons:

1. Their physiology of pregnancy is well studied.
2. They have primarily singleton and twin pregnancies.

Fig. 3 Uterine and umbilical (A) oxygen uptakes and (B) blood flows during the last 0.5 (50%) of pregnancy in cows. Data taken from Reynolds, L.P., Ferrell, C.L., Robertson, D.A. and Ford S.P. (1986). Metabolism of the gravid uterus, foetus and uteroplacenta at several stages of gestation in cows. *Journal of Agricultural Science, Cambridge* 106, 437–444 and were determined in vivo. Data are similar for other mammals.

3. They have a relatively long gestation (145–150 days).
4. The gravid uterus can be chronically instrumented (e.g., with blood flow probes).
5. Large amounts of tissue can be collected from the gravid uterine tissue, including the placenta.
6. One can examine multiple stages of pregnancy.
7. Compromised pregnancies exhibit complications similar to those of humans.
8. The structure and function of the placental blood vessels is similar to that of other mammals, including humans.

Using various sheep models of compromised pregnancy, we and others have shown that placental angiogenesis is altered, resulting in reduced placental vascular development, or vascularity, in association with reduced maternal placental (gravid uterine) and fetal placental (umbilical) blood flows. These models of compromised pregnancy include overfed adolescents, multiple pregnancies (specifically singletons vs. triplets), heat stress, underfed adults and adolescents, maternal age (adolescent vs. adult pregnancies), and maternal genotype (Table 1). These observations emphasize the close relationship between placental angiogenesis and placental blood flows. Similar observations of altered placental vascular development in growth-restricted fetuses have been observed for humans (Fig. 7).

Perhaps the most compromised of all pregnancies are those resulting from the use of assisted reproductive technologies (ART), including embryos derived from in vitro fertilization procedures or from cloning. For example, after transfer of in vitro-fertilized embryos in humans and livestock only around 40% or less survive to birth. Because of this we and others have used ART pregnancies

Fig. 4 (A) Changes in capillary area, number, and surface densities of maternal placenta (caruncle) and fetal placenta (cotyledon) from day 20 to 140 of gestation (length of gestation 145–150 days) in sheep; (B) Empirical model of the pattern of capillary growth of the maternal caruncle and fetal cotyledon based on the data in (A); and (C) Scanning electron micrographs of vascular casts of the maternal caruncle and fetal cotyledon on day 90 of gestation—note how similar the micrographs look to the empirical model presented in (B). Modified from (A and B) Borowicz, P.P., Arnold, D.R., Johnson, M.L., Grazul-Bilska, A.T., Redmer, D.A. and Reynolds, L.P. (2007). Placental growth throughout the last two-thirds of pregnancy in sheep: Vascular development and angiogenic factor expression. *Biology of Reproduction* 76, 259–267 and (C) Hafez, S., Borowicz, P., Reynolds, L. and Redmer, D. (2010) Maternal and fetal microvasculature in sheep placenta across several stages of gestation. *Journal of Anatomy* 216, 292–300.

as models for not only highly compromised pregnancies but also to determine whether any vascular defects were observed very early in pregnancy. As shown in [Table 2](#), both in vitro fertilized and cloned (parthenogenetic, meaning in vitro activated to develop but with only maternal genes) embryos from very early in pregnancy (day 22 after mating) showed many defects in growth as well as altered placental vascularization, angiogenic factor expression, DNA methylation, steroid receptor expression, and markers of diapause (embryonic quiescence). These data support the concept that placental vascular defects begin very early in pregnancy and result in poor fetal growth and development.

(2011). Review: The angiogenic and vasodilatory utero-placental network. Placenta. 32 Suppl 2, S170–S175.

Conclusions

Although it seems that placental vascular defects, which probably have their origins very early in pregnancy, are major factors contributing to poor fetal growth and development, and perhaps even have long-term consequences for the offspring, we have much to learn about the mechanisms that determine not only poor placental angiogenesis but also how that impacts fetal growth and development.

Table 1 Fetal and placental weights, placental vascularity, and maternal placental (gravid uterine) and fetal placental (umbilical) blood flows in various models of compromised pregnancy in sheep^a

Model	Fetal wt	Placental wt	Placental vascularity	Gravid Ut blood flow	Umbilical blood flow
Overfed adolescent	–20%–40%	–20–45%	–31%	–36%	–37%
Multiple pregnancy	–30%	–37%	–30%	–23%	–

^aAll groups compared with normal embryos from natural mating.Taken from Reynolds, L.P., Borowicz, P.P., Palmieri, C. and Grazul-Bilska, A.T. (2014). Placental vascular defects in compromised pregnancies: Effects of assisted reproductive technologies and other maternal stressors. In Zhang, L. and Ducsay, C.A. (eds.) *Advances in fetal and neonatal physiology (Advances in Experimental Medicine and Biology 814)* pp. 193–204. New York: Springer Science+Business Media.

For example, as shown in [Table 2](#), even embryos derived in vivo from natural pregnancies, when subjected to what we thought was the fairly ‘mild’ insult of embryo transfer (flushing from the FSH-treated donor’s uterus and transfer to the recipient’s uterus, which takes only about 20–30 min, during which the embryo is in vitro), show many of the same defects as in vitro fertilized or cloned embryos. At the very least, this tells us that our in vitro conditions are not optimal. In fact, several research groups have now shown that culturing embryos in the presence of natural oviductal secretions (and fertilization and early embryonic development take place in the oviduct) can improve the outcome of in vitro fertilization. This is very interesting, as the oviductal fluid contains a very complex mixture of oviduct- and serum-derived factors that support fertilization and early embryonic development.

In addition, we must investigate whether defects in placental angiogenesis affect fetal growth and development in many or only a few mammalian species. At the very least, we know that sheep (and probably other ruminants like cows) and humans exhibit similar defects in placental angiogenesis in pregnancies in which fetal and placental growth are compromised.

Lastly, we need to continue to pursue therapeutic (e.g., sildenafil) and management (e.g., improved maternal nutrition) strategies to improve placental angiogenesis and thereby fetal growth and development, as these problems, which probably also contribute to miscarriage (also termed spontaneous abortion), have major socioeconomic consequences.

Placental Transfer

Thomas Jansson, University of Colorado, Aurora, CO, United States

Introduction

Of all the diverse functions performed by the human placenta, transfer of oxygen, ions, and nutrients is of particular importance for normal fetal growth and development. This article will briefly review the pathways for placental transfer, discuss the key differences between nonmediated and mediated transport and outline the principal factors influencing placental transfer. Subsequently, we will summarize key characteristics of transfer of oxygen, water, and ions across the human placental barrier.

Pathways of Placental Transfer

Solute transfer across epithelia can occur by *paracellular* (i.e., via water-filled channels) or *transcellular* pathways. In contrast to classical epithelia, such as in the kidney and intestine, the transporting epithelium of the human placenta (the syncytiotrophoblast) lacks intercellular spaces with tight junctions. However, physiological evidence, including a correlation between the rate of transplacental flux of a certain solute and its diffusion coefficient in water, suggests that paracellular transfer across the human placenta takes place via transtrophoblastic channels. Moreover, the existence of transtrophoblastic channel is supported by the transfer of large molecules such as alpha-fetoprotein across placental cotyledons perfused in vitro and the observation that fetal blood cells are present in the maternal circulation in vivo. However, the total area occupied by these putative water-filled channels across the human placental barrier is likely to be very small because the syncytiotrophoblast is able to maintain substantial maternal–fetal concentration differences for a large number of solutes including amino acids and calcium. As a consequence, the predominant pathway for transfer across the human placental barrier is transcellular, largely mediated by transporter proteins expressed in the syncytiotrophoblast plasma membranes. The morphological structures corresponding to the transtrophoblastic channels supported by the functional data have yet to be identified. The existence of trophoblast denudations associated with fibrin deposits supports the idea that breaks in the syncytial barrier opens temporary water-filled pathways between the maternal and fetal circulations, which may constitute the morphological correlate to the postulated transtrophoblastic channels (Brownbill et al., 1995).

Nonmediated and Mediated Transport

Placental transfer can be *nonmediated* (not involving any form of specific transport mechanism) or *mediated* (dependent on specific transport mechanisms). The rate of nonmediated transfer is determined by the physical and chemical properties of the molecules, including the charge, size, lipid solubility, and degree of protein binding. Specifically, a solute with high electrical charge, molecular weight and degree of protein-binding and low lipid solubility is expected to cross the placental barrier very slowly, if at all. The nonmediated placental transfer of pharmaceutical drugs is determined by similar factors. For example, in the class of anticoagulants, the placental barrier is virtually impermeable to heparin because of its high molecular weight and charge, whereas orally active drugs such as dicumarol crosses the placental barrier without major restriction because of its relatively low molecular weight (Bajoria and Contractor, 1992). However, the transfer of drugs across the human placenta is influenced by a number of factors beyond physical–chemical properties because many drugs are subjected to mediated uptake, metabolism by cytochrome 450 enzymes and/or extrusion from the syncytiotrophoblast by efflux pumps such as P-glycoprotein (Syme et al., 2004).

The syncytiotrophoblast represents the primary barrier for movement of most solutes from the maternal to the fetal circulations (Fig. 1). Specifically, transfer across the two polarized plasma membranes of the syncytiotrophoblast, the apical or microvillous plasma membrane (MVM) directed to maternal blood in the intervillous space and the basal plasma membrane (BM) facing the fetal capillaries constitutes the limiting step. Maternal fetal-exchange of most nutrients and ions occurs by mediated transfer, largely mediated by transporter proteins expressed in the syncytiotrophoblast plasma membranes. *Facilitated transport* (or *facilitated diffusion*) is defined as a mediated transport not requiring energy expenditure, as exemplified by placental glucose transfer, which is mediated by facilitative glucose transporters expressed in the syncytiotrophoblast MVM and BM. Transplacental transport may also be facilitated by the expression of receptors in the MVM (e.g., the transferrin receptor, which binds transferrin–iron complex in maternal blood thereby facilitating the placental uptake of iron) or binding proteins in the syncytiotrophoblast cytosol (such as fatty acid binding proteins). *Active transport* involves energy consumption, either directly (primary active transport) or indirectly (secondary/tertiary active transport). An example of primary active transport in the placenta is calcium efflux across the BM mediated by Ca^{2+} -ATPase. Moreover, Na^{+} -dependent amino acid transport represents an example of a secondary active transport mechanism.

Endocytosis/transcytosis plays an important role in the transplacental transfer of IgG, iron, and lipoproteins (Fuchs and Ellinger, 2004) and represents a specialized form of transport, which may be nonmediated or mediated. The endocytotic/transcytotic process is initiated by the formation of an intracellular vesicle through the invagination of the plasma membrane on one side of the syncytiotrophoblast. Vesicles may then be transported to the opposite side of the cell where the vesicle content is released into the extracellular space following fusion of the vesicles with the plasma membrane. Endocytosis/transcytosis is nonmediated when vesicles

Fig. 1 Key properties of the placental barrier influencing transfer rate. See text for details. (1) Total effective surface area; (2) Characteristics of the syncytiotrophoblast microvillous plasma membrane (MVM), including passive properties such as lipid composition and fluidity, and expression of transporters, channels, enzymes and receptors; (3) Cytosolic binding proteins; (4) Metabolic interconversion or catabolism in the cytoplasm; (5) Characteristics of the syncytiotrophoblast basal plasma membrane (BM) including passive properties such as lipid composition and fluidity, and expression of transporters, channels, enzymes, and receptors; (6) Transtrophoblastic channels; (7) Diffusion across basement membrane, villous core and capillary endothelium.

incorporate fluid and any dissolved solute (fluid-phase endocytosis) and subsequently are transferred across the syncytium as a consequence of the random motion affecting all particles suspended in a fluid. Mediated endocytosis, on the other hand, involves the binding of ligands to plasma membrane receptors, which initiates the invagination of the plasma membrane and vesicle transfer across the syncytiotrophoblast cytosol may be facilitated by specific components of the cytoskeleton.

Flow-Limited and Diffusion-Limited Transfer

Placental transfer can be limited by the diffusion across the placental barrier (“diffusion-limited” transport) and/or by the rate of uteroplacental and umbilical blood flows (“flow-limited” transport). For example, the transfer of nutrients, which in most cases is mediated by transporters, binding proteins and/or receptors expressed in the syncytiotrophoblast plasma membranes or cytosol, is predominantly diffusion-limited. In contrast, placental transfer of oxygen is blood flow limited because it is a small molecule with high lipid solubility, which rapidly diffuses across the syncytiotrophoblast and fetal capillary endothelium. This is the reason why short-term reductions in placental blood flows affect the transfer of oxygen more than nutrient transport.

Factors Determining the Rate of Placental Transfer

The driving forces and the properties of the placental barrier are the two primary factors governing the rate of placental transfer. The relative importance of these two factors in determining transfer rate is largely dependent on the molecule in question. This section will provide a general discussion of these factors.

The main driving forces for nonmediated transfer and for facilitated diffusion are differences in concentrations and electrical potential, albeit potential differences affect only charged molecules. In addition, osmotic and hydrostatic pressure differences constitute the driving forces governing the movement of water across the placental barrier. Bulk water through transtrophoblastic channels will also carry solutes. Finally, hydrolysis of ATP is the driving force for active transport.

The transplacental potential difference is generated by active ion transport. In contrast to many animals, the maternal-fetal potential difference in the human is small, -2.7 mV (fetal negative) in mid-gestation and close to zero at term (Mellor et al., 1969). However, this potential difference is measured across the entire placental barrier and larger potential differences across individual components of the barrier constitutes powerful driving forces for charged molecules. For example, the *in vitro* potential difference across the MVM has been reported to be -32 mV in early first trimester and -21 mV at term (Birdsey et al., 1997).

The barrier properties that influence the rate of placental transfer are illustrated in [Fig. 1](#). The available effective exchange surface area is a key determinant of net transfer. Changes in exchange area can be due to structural factors, which may alter the total area available for exchange, or impaired blood flow in the umbilical or uteroplacental circulation removing a section of the placental barrier from effective exchange. Lipid composition, membrane fluidity and other passive characteristics of the MVM (#2 in [Fig. 1](#)) and BM (#5) are factors of particular importance influencing nonmediated transport. The expression and activity of transporters (e.g., amino acid transporters), channels, enzymes (for example MVM lipoprotein lipase) and receptors (e.g., the Fc receptor in MVM, mediating uptake of IgG) in the two polarized plasma membranes of the syncytiotrophoblast are critical for mediated transport. Indeed, for most solutes the transfer across the syncytiotrophoblast MVM and/or BM are the rate-limiting and actively regulated step in maternal-fetal exchange. The mediated transfer of some molecules, including fatty acids and calcium, requires the presence of a cytosolic binding protein (#3). Not all solutes transferred across the placenta are inert but are subjected to metabolism, including glucose and amino acids, in the syncytiotrophoblast (#4), which represent an additional property of the placental barrier that influences the overall transfer rate. Molecules transferred across the BM must move across the basement membrane, villous core and capillary endothelium (#7) to reach fetal blood in the fetal placental capillaries.

Placental Oxygen Transfer

Oxygen is critical for oxidative metabolism in the placenta and fetus, generating ATP for energy requiring processes such as active transport and protein synthesis. In addition, oxygen availability regulates placental growth, trophoblast gene expression, and invasion. Fetal hypoxemia in, for example, the sheep ([Jacobs et al., 1988](#)) is associated with fetal growth restriction, however the cause-and-effect relationship between limitation in oxygen supply and reduced fetal growth is unclear because interventions resulting in fetal hypoxemia alter a multitude of other factors that could be the cause of the growth restriction. However, more conclusive evidence for a mechanistic link between hypoxia and restricted fetal growth has been obtained in the chick embryo, a model in which the effects of changes in oxygenation on the fetus can be investigated in isolation ([Giussani et al., 2007](#)).

Although direct evidence in the human is lacking, placental oxygen transfer is believed to be limited by blood flows rather than by diffusion across the barrier. This model is primarily based on studies in the sheep (reviewed in [Carter, 1989](#)) demonstrating that there is a linear correlation between placental blood flow and fetal oxygen delivery following acute reductions in either umbilical or uterine blood flow. It is notable, however, that despite the decrease in oxygen delivery fetal oxygen consumption was maintained by increased umbilical oxygen extraction. This homeostatic mechanism is highly beneficial in response to physiological short-term reductions in uterine blood flow, which occur in labor and during physical exercise.

In response to chronic reductions in uterine or umbilical blood flows, however, fetal oxygen consumption is decreased and fetal growth is restricted.

Because of the flow limitation of oxygen transfer, the geometry of placental blood flows affects the efficiency of oxygen transport across the placental barrier (reviewed in [Faber and Thornburg, 1983](#)). The possible types of geometric arrangement of blood flows on either side of the placental barrier fall into a number of partly overlapping categories or models, which may explain differences in oxygen transfer efficiencies between species. The counter-current exchanger, in which blood in the fetal and maternal circulations flow in opposite directions in vessels running parallel to each other, represents the most efficient geometric arrangement. The concurrent exchanger, where fetal and maternal blood flows in the same direction in vessels that are arranged in parallel, is less efficient than the counter-current arrangement. The human placenta has a “multivillous” geometry of placental blood flows, with efficiency in between the counter-current and the concurrent model.

With maternal arterial pO_2 at approximately 100 mmHg and pO_2 in the umbilical vein in the range of 34–41 mmHg at the end of pregnancy, there is a large gradient facilitating maternal-fetal oxygen transfer. A higher hemoglobin concentrations in fetal blood, resulting in a significantly higher oxygen carrying capacity, and a higher affinity of fetal (HbF) hemoglobin for oxygen as compared to maternal hemoglobin (HbA) constitute other factors promoting the movement of oxygen from the maternal to the fetal circulation.

In vascular beds such as in the brain and kidney there is extensive auto-regulation and muscle is characterized by reactive hyperemia, which are processes that adapt blood flow in response to changes in either oxygen delivery or demand. Because the placental vasculature does not exhibit auto-regulation or reactive hyperemia, short-term regulation of placental oxygen transfer is largely limited to changes in fetal oxygen extraction as discussed above. As an important example of long-term regulation of placental oxygen transfer, fetal polycythemia (increased hematocrit) develops in response to chronic hypoxemia.

Placental Transfer and the Maintenance of Fetal Acid–Base Balance

For maintenance of its acid–base balance the fetus is entirely dependent on placental transfer of carbon dioxide, protons, and lactate ([Fig. 2](#)).

Carbon dioxide

Fetal and placental oxidative metabolism results in the generation of large amounts of carbon dioxide, characterized as a “respiratory acid” because it is in equilibrium with carbonic acid that can rapidly produce protons. CO_2 is eliminated across the placental barrier predominantly via diffusion of dissolved gas, which is rapid given the high lipid solubility of carbon dioxide. One of the characteristic maternal physiological adaptations to pregnancy is hyperventilation and as a result arterial pCO_2 is lower in pregnancy (between 26 and 34 mmHg) as compared to the nonpregnant woman (38–42 mmHg). With umbilical vein pCO_2 at term in

Fig. 2 Placental transport of carbon dioxide, protons, and lactate. Carbon dioxide rapidly diffuses across the placental barrier as dissolved gas. Metabolically produced protons are eliminated across the placenta, mediated by MCT1 H^+ /lactate co-transport in the BM, followed by extrusion of protons in exchange for sodium across the MVM and mediated by the sodium-proton exchanger (NHE). Transporters for excitatory amino acid transporters (EAAT), which co-transport Na^+ , H^+ and anionic amino acids, may contribute to the uptake of protons across the BM. CA, carbonic anhydrase.

the range of 38 and 45 mmHg, there is a substantial diffusion gradient across the placental barrier promoting fetal-maternal CO_2 transfer. CO_2 is predominantly present as H^+ and bicarbonate ions in blood and is converted at the placental barrier to CO_2 , catalyzed by the action of carbonic anhydrase expressed in erythrocytes, endothelial and trophoblast cells (Muhlhauser et al., 1994). A respiratory acidosis develops in response to acute reductions in uteroplacental and/or umbilical blood flows, however this acid-base balance disturbance is rapidly normalized following re-establishment of adequate blood flows.

Protons

A net production of protons by fetal metabolism cannot be eliminated by transport of CO_2 across the placental barrier but require transfer of protons from the fetal to the maternal circulation or movement of bicarbonate from the mother to the fetus. The latter process is unlikely to be important given that transport mechanisms mediating bicarbonate transfer from the maternal to the fetal circulation has yet to be identified.

The human sodium-proton exchanger (NHE, SLC9) gene family is comprised of nine transporter isoforms, NHE1–9, most of which mediate sodium-dependent transport of protons out of the cell. NHE1 is the predominant isoform in the MVM, which, with some contribution from NHE 2 and 3, exports protons from the cytosol of the syncytium into maternal blood in the intervillous space (Fig. 2), thereby playing a critical role in the maintenance of syncytiotrophoblast pH (Powell and Illsley, 1996). Placental NHE activity is regulated by a wide range of factors (Sibley et al., 2002), including epidermal growth factor, sphingosine-1-phosphate, aldosterone and cortisol, which all have been reported to activate the transporter in term villous fragments.

Lactate levels are significantly higher in the fetal circulation than in maternal blood and lactate is used as a source of energy by the fetal heart, brain, and skeletal muscle. The placenta serves both as a net producer of lactate under normoxia and as a site of clearance of fetal lactate when produced in excess during fetal hypoxia. Members of the monocarboxylate transporter (MCT) family (SLC19) represent the main transporters of lactate by mediating H^+ /lactate co-transport. MCT4 is highly expressed in the MVM, whereas MCT1 is believed to be the main lactate transporter in the BM.

Fig. 2 provides a simplified model of the current understanding of the main mechanisms involved in placental regulation of fetal and placental pH. CO_2 readily diffuses across the placental barrier as dissolved gas. Metabolically produced protons are transported across the BM by the H^+ /lactate co-transporter MCT 1 and subsequently transferred across the MVM mediated by NHE1. Excitatory amino acid transporters (EAAT), mediating the cellular uptake of anionic amino acids coupled to the co-transport of Na^+ and H^+ may also contribute to the transport of protons from the fetal compartment into the syncytiotrophoblast.

Placental Transfer of Sodium, Potassium, and Chloride

Sodium is the predominant extracellular cation, a main contributor to crystalloid osmotic pressure and an important determinant of extracellular volume. In classical epithelia, such as in the kidney, sodium enters the cell passively across the apical plasma

membrane by a wide range of mechanisms, followed by active transport across the basolateral membrane mediated by $\text{Na}^+\text{K}^+\text{-ATPase}$. Although syncytiotrophoblast sodium handling is organized according to the same general principles, the placental transporting epithelium also has unique properties with respect to sodium transport.

Na^+ -dependent co-transporters expressed in the MVM utilize the inwardly directed sodium gradient to drive the uptake of, for example, amino acids, phosphate, biotin, and succinate from the intervillous space into the syncytiotrophoblast or the efflux of protons via exchange mechanisms. Low syncytiotrophoblast intracellular sodium concentrations are maintained by $\text{Na}^+\text{K}^+\text{-ATPase}$, which, in contrast to the transporting epithelium in the kidney and intestine, is expressed and active in both BM (Whitsett and Wallick, 1980; Johansson et al., 2000) and MVM (Johansson et al., 2000) of the human syncytiotrophoblast.

Potassium, the predominant intracellular cation, is actively transported into the cell mediated by $\text{Na}^+\text{K}^+\text{-ATPase}$. Energized by the large outwardly directed gradient, potassium exit the syncytium passively through an array of different potassium channels present in the MVM and BM. The mechanisms for transplacental K^+ transport remain elusive because the identity of the channels participating in K^+ transfer across the placenta, the polarization of potassium channels to the MVM and BM and which are primarily involved in cellular potassium homeostasis are largely unknown.

Chloride is the most abundant extracellular anion, which is transferred across plasma membranes mediated by multiple mechanisms including co-transport with Na^+ (uptake) or K^+ (efflux), exchange with bicarbonate or through channels. The anion exchanger 1 (AE1, SLC4A1) is expressed and active in the MVM throughout gestation but not in the BM. Additional chloride transporters that have been shown to be active in the trophoblast include a high conductance (maxi) chloride channel, intermediate DPC-inhibitable, small PKA/ATP/cAMP activated chloride channels, CL15, CFTR and MDR1 P-glycoprotein. However, the physiological role of these chloride transporters and channels remains elusive and how they mediate transcellular chloride transport is not well understood. Because the concentration and electrical gradients favor passive chloride movement in the fetal-maternal direction, net transplacental chloride transport cannot be mediated by passive transport.

Water Transport

It has been estimated that the human fetus accumulates 22 mL of water per day close to term and because only around 20% of this can be accounted for metabolically produced water by the fetus; most of the water must be transferred from the maternal circulation (Stulc, 1997). The driving forces and pathways for net water movement from the mother to the fetus remain to be fully established. However, reported values for pressures in the umbilical vein and intervillous space demonstrate that hydrostatic pressure differences across the human placenta in vivo promote transfer of water in the fetal-maternal direction. Moreover, the colloidal osmotic pressure is slightly higher in the maternal than in the fetal circulation, establishing another driving force moving water towards the mother. As a consequence, net transplacental movement of water must be driven by an osmotic gradient of solutes.

Intriguingly, investigators have not been able to demonstrate such a gradient in vivo. Studies demonstrating significant water permeability of the syncytiotrophoblast plasma membranes (Ilsley and Verkman, 1986; Jansson and Ilsley, 1993) provide one possible explanation because this suggests that a net water accumulation of 15–20 mL/day could easily be accounted for by a solute gradient across the placental barrier small enough to be within the margin of error of standard osmolarity measurements (Jansson and Ilsley, 1993). In line with a model that has been proposed for the rat placenta (Stulc, 1997), available data suggests that actively transported solutes into the fetal side of the human placental barrier generate a small osmotic gradient, which promotes water movement via a transcellular pathway. Most of this water then returns to the maternal circulation via transtrophoblastic channels driven by the hydrostatic and colloid osmotic pressure gradients.

Cells expressing water channels, or aquaporins (AQP), in the plasma membranes have a water permeability that is 2–50 fold higher than cells lacking water channels. There are at least 13 mammalian AQP isoforms, some of which also function as glycerol transporters, including AQP3, 7, and 9. Moreover, AQP9 transports amino acids and sugars in addition to water and AQP8 also mediates the transport of ammonium. Although AQP3, 8, and 9 are expressed at the RNA and protein level in the human syncytiotrophoblast, the functional role of these aquaporins in the syncytiotrophoblast remains to be determined because efforts to demonstrate AQP mediated water permeation across isolated syncytiotrophoblast MVM and BM have been unsuccessful (Jansson and Ilsley, 1993). It has been proposed that placental aquaporins are important for solute transport because all three aquaporins expressed in the syncytiotrophoblast either transport glycerol (AQP3 and 9) or ammonium (AQP8) in addition to water and (Damiano et al., 2001).

Calcium Transport

Total accretion of calcium in the human fetus is 30 g across gestation, the majority occurs in the third trimester when fetal bone mineralization occurs. As in other cells, calcium is a critical intracellular messenger in the syncytiotrophoblast, which necessitates that cytosolic calcium concentrations are maintained at levels that are four magnitudes lower than extracellular concentrations. The transfer of calcium across the syncytiotrophoblast takes place in three distinct steps (reviewed in Belkacemi et al., 2005). Following Ca^{2+} entry into the cell across MVM, calcium moves through the cytosol associated with calcium binding proteins and subsequently Ca^{2+} ATPase mediates the active transport of the ion across BM.

Members of the transient receptor potential (TRP) gene family, in particular TRPV5 and 6, are calcium-selective channels functioning as apical calcium entry mechanisms in transporting epithelia. TRPV6 is highly expressed in the human placenta and functional in cultured primary human trophoblast (PHT) cells (Moreau et al., 2002). Store operated channels (SOC), which are

calcium channels in the plasma membrane activated by depletion of intracellular calcium stores, may serve as an additional type of MVM entry mechanism because SOCs are expressed and functional in syncytiotrophoblast of term villous fragments (Clarson et al., 2003). Moreover, ATP promotes calcium influx into trophoblast cells mediated by interaction with the P2 purinergic receptor family. In addition to these calcium-selective channels, a range of nonselective cation channels, such as Polycystin-2, have been reported to be expressed and active in the MVM, which also may contribute to Ca^{2+} entry into the syncytiotrophoblast.

Following calcium entry into the cytoplasm of the syncytiotrophoblast, the ion is rapidly stored in intracellular compartments or bound to calcium-binding proteins including calmodulin and calbindin. Sequestration of calcium into the endoplasmic reticulum allows for regulation of cytosolic calcium concentrations by uptake to and release from this store in response to DAG-PKC-IP3 signaling. Intracellular calcium binding proteins transport calcium through the cytoplasm while maintaining very low intracellular concentrations of free calcium. Whereas calbindin- D_{9k} has been found to be an important calcium binding protein in the rat placenta, the identity of the key calcium binding proteins in the human syncytiotrophoblast remains to be fully established.

The $\text{Na}^+/\text{Ca}^{2+}$ exchanger and the calcium pump (or Ca^{2+} ATPase) represent the two fundamental mechanisms by which Ca^{2+} is actively transported out of the cell against a large electrochemical gradient. Whereas $\text{Na}^+/\text{Ca}^{2+}$ exchange does not play a major role in Ca^{2+} efflux from the human syncytiotrophoblast, the plasma membrane Ca^{2+} ATPase (PMCA) is highly expressed and functional in the BM. Of the four PMCA isoforms (PMCA1–4), PMCA1 and 4 are ubiquitously expressed, including in the syncytiotrophoblast basal plasma membrane (Strid and Powell, 2000). The activity of the BM calcium pump was found to increase significantly in the third trimester suggesting an increased transport capacity during the critical period of rapid mineralization of the fetal skeleton (Strid and Powell, 2000).

The mechanisms regulating placental calcium transport are only beginning to be determined. The role of parathyroid hormone (PTH), calcitonin and 1,25-dihydroxycholecalciferol (vitamin D) in the regulation placental calcium transport has been studied in animal models (reviewed in Stulc, 1997). These studies have revealed that vitamin D stimulates and calcitonin inhibits placental calcium transport in the sheep but not in rat. However detailed studies of the influence of the three main calcium-regulating hormones on calcium handling in the human placenta are largely lacking. Parathyroid hormone related peptide (PTHrP) has emerged as the primary hormonal regulator of placental calcium transport. PTHrP is synthesized by a range of fetal tissues including the parathyroid glands, as a 141 amino acid pro-hormone. Subsequently the pro-hormone is cleaved into several fragments of which a mid molecule fragment PTHrP-(38–94) is of particular importance for the regulation of placental calcium transport.

A fragment (67–86) of the PTHrP mid-molecule was reported to maintain the calcium gradient across the sheep placenta. This observation was subsequently confirmed using the highly conserved mid-region secretory fragment of PTHrP (PTHrP (38–94) amide). Moreover, homozygous deletion of the PTHrP gene in mice resulted in decreased placental transport of calcium and dissipation of the normal Ca^{2+} concentration gradient across the placental barrier (fetal Ca^{2+} concentrations > maternal). PTHrP (38–94) activates human placental Ca^{2+} ATPase (Strid et al., 2002), suggesting that fetal PTHrP regulates placental calcium transport also in pregnant women.

Placental Nutrient Transport

Laura B James-Allan, Theresa Powell, and Thomas Jansson, University of Colorado, Aurora, CO, United States

Introduction

The placenta constitutes the primary interface between the mother and fetus with a multitude of functions, including nutrient and respiratory gas transport, waste removal, providing an immunological barrier, as well as acting as an endocrine organ. The placenta produces and secretes a wide range of hormones, cytokines, and growth factors. The syncytiotrophoblast (ST) functions both as a barrier and the transporting epithelium of the placenta mediating vectorial transport of a wide range of molecules. At term, the fetal and maternal circulations are separated by two cell layers: the ST and the fetal capillary endothelium. Fetal placental capillaries are nonfenestrated and are linked to neighboring endothelial cells (EtC) by junctional complexes, allowing relatively unrestricted intercellular passage of small molecules such as glucose and amino acids, but restricting transfer of larger molecules, including immunoglobulins. These larger molecules must be transported across the EtC via vesicular transport. Thus, ST acts as the primary barrier between the maternal and fetal circulations, thereby controlling placental transfer of small solutes. The ST is made up of a multinucleated continuous layer of specialized epithelial cells that line the placental villous tree vascular structure. The ST consists of two polarized plasma membranes: the fetal facing basal plasma membrane (BM) adjacent to the fetal capillaries (FC) and the maternal facing apical brush border or microvillus plasma membrane (MVM) which is in direct contact with maternal blood (Fig. 1). The MVM has a large surface area to allow for rapid transport of nutrients from the maternal circulation in to the ST, nutrients are subsequently transported across the BM in order to reach the fetus.

A wide array of transporters are expressed in the plasma membranes of the ST and the polarized localization of transporters with differing characteristics to the two membrane surfaces allows for vectorial transport across the barrier. Placental nutrient transport is a critical determinant of fetal growth. Fetal overgrowth and intra-uterine growth restriction (IUGR) are two important pregnancy complications associated with an increased perinatal morbidity and mortality, as well as an increased risk of developing cardiovascular and metabolic disease later in life. Both of these conditions represent pathological fetal growth and are associated with distinct changes in placental nutrient transport. In IUGR, a range of placental nutrient and ion transporters are downregulated, whereas fetal overgrowth is associated with an increased placental nutrient transport capacity. These observations in women, together with cause-and-effect experiments in animal models, have led the suggestion that changes in placental nutrient transport directly contribute to or are causative in the development of IUGR and fetal overgrowth. Thus, unraveling the mechanisms and regulation of placental nutrient transport is critical for our understanding of the pathophysiology of important pregnancy complications and may provide new fundamental knowledge that can be used to develop novel intervention strategies.

Fig. 1 The syncytiotrophoblast (ST) constitutes the transporting epithelium in the human placenta and is characterized by the fetal facing basal plasma membrane (BM) adjacent to the fetal capillaries (FC) and the maternal facing microvillus plasma membrane (MVM). Fetal placental capillaries allow unrestricted movement of small molecules through junctional complexes in endothelial cells (EtC). (A) Amino acids are delivered to the fetus by membrane bound transporters, such as system A which is predominantly found on the MVM plasma membrane and transports neutral amino acids, and system L transporters, which exchanges essential for nonessential amino acids on both the MVM and BM. (B) Glucose is transported from maternal blood to the fetus by GLUT transporters on the MVM and BM, with greater expression on the maternally facing MVM. (C) Fatty acids from the maternal circulation are transported in to the ST by fatty acid transporters (FAT), fatty acid transporter proteins (FATP), and placental specific plasma membrane fatty acid binding protein (FABPpm). Fatty acid binding proteins (FABP) are localized to the ST cytosol, with FAT and FATP on the BM transporting fatty acids from the ST to the fetus.

Amino Acids

Amino acids are essential for the growth of the fetus because they are required for protein synthesis, energy production, oxidative metabolism, and biosynthetic pathways. Amino acids are delivered to the fetus through transporters on both ST membranes of the placenta (Fig. 1A). Amino acid concentrations are higher in the fetal compartment compared to maternal plasma, indicating that amino acids are actively transported from maternal blood to the fetus via the placenta. The amino acid transport process utilizes energy and there are two energy dependent transporters, accumulative transporters and exchangers, as well as facilitated efflux transporters that do not require energy. Accumulative transporters mediate the uptake of amino acids against their concentration gradients, often energized by the co-transport of extracellular sodium. These transporters establish high intracellular concentrations of nonessential amino acids and efflux of these amino acids provides a driving force for uptake of essential amino acids from the maternal circulation by exchange transporters. Accumulative transporters are predominantly found in the MVM of the ST, however some are also present in the BM, but to a lesser extent. Amino acid exchangers transport one amino acid across the ST in exchange for another amino acid. This changes the composition of the amino acid pool without altering the total concentration. Exchangers are found on both the MVM and BM membranes, and are specific for amino acids that are not transported by accumulative or facilitative transporters. Facilitated transporters are primarily located on the BM, where they allow transport of specific amino acids down their concentration gradient, therefore typically mediating amino acid efflux into the fetal circulation.

Amino acid transporters can be categorized using a variety of characteristics, including substrate specificity and dependence on, for example, pH and charge and the presence of sodium and chloride. More than 20 different amino acid transporter systems have been described in the human placenta, some of which are listed in Table 1. The most well studied amino acid transporters found in the placenta are system A and system L.

System A

The system A transporter is a Na^+ dependent accumulative transporter, transporting small zwitterionic, nonessential neutral amino acids, including alanine, glycine, and serine. The system A transporter is made up of three homologous isoforms, SNAT1, SNAT2, and SNAT4, which are encoded by the *SLC38* gene family, *SLC38A1*, *SLC38A2*, and *SLC38A4*, respectively. SNAT1 and SNAT2 are functionally similar, whereas SNAT4 has a lower affinity for neutral amino acids. All three isoforms are expressed in the plasma membranes of the ST and are highly polarized to the MVM. The expression of these isoforms differs throughout gestation; SNAT4 is highly expressed during the first trimester, whereas SNAT1 plays a more important role in system A activity in the term placenta (Desforges et al., 2009, 2010). MVM system A activity increases between the first trimester and term, matching the increasing needs of the growing fetus (Mahendran et al., 1994). System A activity leads to high intracellular concentration of nonessential amino acids, which are exchanged for extracellular essential amino acids via system L. Therefore, system A is critical for the transport of both nonessential and essential amino acids.

Activation of mechanistic target of rapamycin (mTOR) promotes system A activity by regulation at the post translational level, involving increased plasma membrane trafficking of the SNAT2 isoform (Rosario et al., 2013). In addition, a range of hormones and growth factors, such as IGF-I, insulin, and leptin, which are upstream regulators of mTOR, are positive regulators of system A (Jansson et al., 2003; Jones et al., 2009; Kniss et al., 1994). Conversely, system A is inhibited by a variety of factors, such as hypoxia, IL-1 β , and growth hormone (Ericsson et al., 2005; Nelson et al., 2003; Thongsong et al., 2005).

Table 1 Key amino acid transport systems in the human term placenta.

System	Characteristics	Preferred substrates	Distribution
<i>Na^+-dependent</i>			
System A	Transports small, zwitterionic, nonessential amino acids. Accumulative transporter	Glycine, serine, alanine, cysteine, glutamine, histidine, asparagine, MeAIB	Microvillus plasma membrane (MVM) Basal plasma membrane (BM) (low abundance)
System ASC	Exchanger	Alanine, serine, cysteine, threonine	BM
System β	Specific for β -amino acids Chloride dependent	B-alanine, taurine	MVM
System X_{AG}^-	Accumulative transporter K^+ -dependent	Glycine, aspartate, cysteine	MVM BM
<i>Na^+-independent</i>			
System L	Transports nonessential branched chain and aromatic amino acids Exchanger transporter	Leucine, phenylalanine, histidine, methionine, leucine, valine, isoleucine	MVM BM
System y^+	Specific for cationic amino acids Uniporter	Arginine, lysine, histidine	MVM BM
System $\text{y}^+ \text{L}$	Transports cationic amino acids Exchanger transporter	Lysine, arginine, histidine, methionine, leucine	MVM BM

System L

System L is a Na^+ —independent transporter of essential amino acids, including L-leucine and L-phenylalanine. System L activity has been demonstrated in both the MVM and BM of the ST, exchanging nonessential amino acids for predominantly essential amino acids. This transporter is a homodimer, made up of a light chain protein, L-type Amino acid Transporter, LAT1 (*SLC7A5*) or LAT2 (*SLC7A8*), covalently linked to a heavy chain transmembrane protein, 4F2hc/CD98 (*SLC3A2*). Protein expression of LAT1 and 4F2hc increases in the placenta from mid-gestation to term (Okamoto et al., 2002). Both LAT1 and LAT2 are expressed in the ST; LAT1 is primarily found in the MVM whereas LAT2 mainly in the BM, although it can also be expressed in the MVM (Kudo and Boyd, 2001; Okamoto et al., 2002). LAT1 and LAT2 both contribute to system L activity in the term placenta, however LAT1 is primarily involved in the uptake of larger neutral amino acids on the maternally facing MVM, whereas LAT2, being prominent on the BM, is responsible for the exchange of nonessential amino acids in the fetal compartment for essential amino acids in the ST cytoplasm (Gaccioli et al., 2015).

The regulation of system L is not as well characterized, however it is known that activity is not regulated by the same factors as system A. Increased intracellular calcium, and activation of protein kinase C and mTOR signaling stimulate system L activity (Okamoto et al., 2002; Roos et al., 2007).

Glucose

Glucose is the main energy source for the placenta and the fetus. As fetal gluconeogenesis is minimal, the fetus is dependent on placental supply of glucose from the maternal circulation. Glucose transport across the ST is carried out by a family of glucose transporters (GLUT) which mediate stereo-specific, sodium-independent facilitated diffusion of glucose down a concentration gradient (Fig. 1B). The maternal circulation has a higher concentration of glucose compared to the fetus, resulting in a net maternal-fetal diffusion gradient for glucose across the ST. This allows for adequate glucose consumption by the placenta, while maintaining a gradient between the interior of the ST and the fetal capillary to allow for net transport to the fetus. GLUTs are expressed in both plasma membranes of the ST, although the expression of GLUTs is highest in the MVM. Glucose uptake across the MVM is believed to be very rapid because of the high abundance of GLUTs in combination with the large surface area of the MVM. The BM, with its lower abundance of GLUT and smaller surface area, is thought to be the rate limiting step in transplacental glucose transport at term.

GLUT1 (*SLC2A1*), the ubiquitous isoform of the glucose transporter family, is the primary glucose transporter in the human placenta at term. Its expression increases over gestation and is present in both ST plasma membranes, with a threefold higher expression in the MVM than BM at term (Jansson et al., 1993). GLUT3 (*SLC2A3*) is highly expressed in the ST in early pregnancy and decreases across gestation (Brown et al., 2011). Corticotropin-releasing hormone (CRH) secreted locally by the ST modulates GLUT1 and GLUT3; CRH levels positively correlate with increasing gestation and therefore are thought to upregulate the expression of GLUT1 and downregulate GLUT3 expression. The insulin-sensitive glucose transporters GLUT4 (*SLC2A4*) and GLUT12 (*SLC2A12*) have been detected in the ST in early gestation placenta, with decreasing expression in late gestation (Ericsson et al., 2005; Gude et al., 2003). Insulin receptors are believed to be more highly expressed in the ST in early gestation compared to term, which correlates with the expression of both GLUT4 and GLUT12 expression (Desoye et al., 1994). This suggests that insulin may be driving the recruitment and/or activation of GLUT4 and GLUT12 transporters during early gestation and therefore playing a primary role in placental glucose uptake in the first trimester of pregnancy. The placenta also expresses GLUT8 (*SLC2A8*), GLUT9 (*SLC2A9*), and GLUT10 (*SLC2A10*) (Bibee et al., 2011; Dawson et al., 2001; Doege et al., 2000). The placenta at term expresses both splice variants of GLUT9, with GLUT9a found on the BM and GLUT9b primarily on the MVM (Bibee et al., 2011). GLUT9 is known to transport fructose as well as glucose, therefore GLUT9 in the placenta may function to transport fructose as well as glucose. However, the functional role of GLUT 8–10 in term placental remains to be established.

Fatty Acids

Fatty acids are essential for the growth of the fetus and development of specific organs and tissues. An ample fetal supply of essential fatty acids (EFA) and long chain polyunsaturated fatty acids (LC-PUFA) are particularly important in the third trimester, when the fetal demand for nutrients is at its peak. Fatty acid concentrations in the maternal plasma increase during pregnancy due to physiological hyperlipidaemia. EFA, such as linoleic acid (LA, 18:2n-6) and α -linolenic acid (ALA, 18:3n-3) are only obtained from the diet. Placental transfer of PUFAs, mainly arachidonic acid (AA, 20:4n-6) and docosahexaenoic acid (DHA, 22:6n-3), to the fetus in the third trimester is critical for normal development of the brain and retina. This is because the fetus is able to synthesize saturated and monounsaturated fatty acids from glucose and ketone bodies, however, neither the placenta nor the fetus can produce EFA or the n-6 and n-3 LCPUFA derivatives, which must be derived from the maternal circulation. The placenta preferentially transfers LC-PUFAs versus other types of fatty acids; this selective LC-PUFA transfer to the fetal circulation is termed “biomagnification.” Fatty acids that are transported across the placenta originate from the maternal circulation, either as nonesterified fatty acids (NEFAs) or esterified fatty acids in triglycerides (TGs) that are carried by lipoproteins, with subsequent metabolism within the placenta.

Triglycerides in maternal lipoproteins are made available for placental transfer via hydrolysis into NEFAs. This is an enzymatic process that requires lipase enzymes. There are two main lipases found in the placenta: lipoprotein lipase (LPL) and endothelial lipase (EL) which are both capable of hydrolysing lipoprotein TGs and phospholipids. LPL and EL are found on both ST plasma membranes, with LPL localized primarily to the MVM and EL also present in the luminal plasma membrane of fetal capillary EtC. LPL primarily hydrolyses TGs, whereas EL predominantly hydrolyses phospholipids, with a small amount of TG activity. LPL activity increases throughout gestation, with higher activity at term compared to the first trimester. Placental LPL activity is regulated by hormones such as estradiol, insulin, IGF-1, and cortisol, however activity is not regulated by pro-inflammatory cytokines, as in other tissues (Magnusson-Olsson et al., 2006). EL expression changes during pregnancy; term placenta expresses higher levels of EL than in the first trimester. Once taken up NEFAs can be re-esterified and deposited as TGs or phospholipids in the cytosol of the ST and then hydrolysed at a later time to be released to the fetal circulation.

Fatty acids can be transported to the fetus via simple diffusion or by facilitated diffusion mediated by transport proteins in the ST of the placenta. A range of proteins implicated in fatty acid transport, including fatty acid translocase (FAT)/CD36, placental specific plasma membrane FA binding protein (pFABPpm), fatty acid transport proteins (FATP), and intracellular fatty acid binding proteins (FABP) are expressed in the ST (Fig. 1C). FATP are a family of integral membrane proteins consisting of six related members, of which five are present in the human placenta. They are believed to be important for the cellular uptake of long-chain fatty acids. FATP1–4 (*SCL27A1–4*) and FATP6 (*SLC27A6*) are expressed in the human placenta, with FATP2, FATP4, and FATP6 being more highly expressed at the mRNA level. FATP1 was first identified in the human placenta, and is expressed in both the MVM and BM. The mRNA expression of FATP1 and FATP4 correlates with levels of maternal DHA (Larque et al., 2006). The especially strong positive correlation of FATP4 with fetal DHA phospholipid levels suggests that FATP4 has an important role in the transfer of LC-PUFAs.

pFABPpm is the only placenta specific fatty acid transporter and is exclusively expressed on the MVM of the ST. Essential FA and LC-PUFA preferentially bind to FABPpm, consistent with the possibility that this transporter is involved in transfer of these fatty acids across the placenta (Campbell et al., 1997). FAT is a glycosylated protein that has been identified on both placental MVM and BM membranes (Campbell et al., 1998). It has multiple ligands, including FFA, collagen, and oxidized low-density lipoproteins. Little is known regarding its function in the placenta, however it is believed to be involved in placental FA transfer.

FABPs are a family of proteins that are expressed in a diverse range of tissues; FABP1, FABP3, FABP4, and FABP5 have all been shown to be expressed, at the mRNA and protein level, in the human placenta at term (Biron-Shental et al., 2007; Campbell et al., 1998). FABP are found within the cytosol of the ST where they traffic fatty acids to sites within the cell for esterification, beta-oxidation or transport to the fetus. Hypoxia enhances the expression of FABP1, 3, and 4, suggesting that FABP supports the transfer of fatty acids in hypoxic conditions. PPAR γ increases the expression of FABP1 and FABP4 (Biron-Shental et al., 2007).

Placental Transport and Fetal Growth

IUGR and fetal overgrowth are both associated with higher perinatal morbidity and mortality as well as an increased risk of cardiovascular and metabolic disease later on in life. When the maternal supply line is unable to deliver adequate amounts of nutrients and oxygen to the placenta, which includes conditions such as compromised utero-placental blood flow, high altitude hypoxia and maternal undernutrition, hormonal (such as low insulin, leptin and IGF-I, and high adiponectin and cortisol) and biochemical signals (such as hypoxia) downregulate key placental functions such as nutrient transport, directly contributing to fetal growth restriction. In contrast, when the maternal supply line delivers an excessive amount of nutrients, such as in maternal obesity and diabetes, signals (including high insulin, leptin and IGF-I and low circulating levels of adiponectin) cause an upregulation of placental nutrient transport, contributing to increased fetal growth. Consequently, the placenta is key in serving as a nutrient sensor and regulating placental nutrient transporters in the ST, summarized in Table 2.

IUGR

IUGR can result from a variety of causes, including placental insufficiency and maternal undernutrition. IUGR is associated with a reduction in nutrient transport and oxygen supply to the fetus, however the mechanisms are still not fully understood. Both utero-placental and umbilical blood flows are typically reduced in IUGR, at least in severe cases, however this is unlikely to fully explain the decreased placental nutrient transfer in this condition.

Fetal nutrient availability is decreased in IUGR. For example, umbilical vein concentrations of essential amino acids are reduced in growth restricted fetuses (Cetin et al., 1992), which is believed to be due to a downregulation of placental amino acid transporters, including reduced activity of the system A amino acid transporter in the MVM in IUGR (Jansson et al., 2002). System L activity is also reduced in both the MVM and BM in IUGR, changes that are believed to contribute to a decreased placental transfer of essential amino acids in IUGR (Jansson et al., 1998). Amino acids are one of the key stimulators of the secretion of fetal insulin, which is one of the primary growth hormones in fetal life. Therefore, a reduction in fetal amino acid availability can directly lead to a decrease in fetal growth. Many IUGR fetuses are hypoglycaemic. However, this appears not to be due to changes in placental glucose transport as the activity and expression of GLUT1, the main glucose transporter in the placenta, is unaltered in MVM and BM of IUGR placentas. GLUT3 protein expression has been reported to be increased in placenta from IUGR pregnancies (Janzen et al., 2013), however the functional consequences remain to be established.

Table 2 Alterations in placental nutrient transporter expression and activity in pregnancy complications

Nutrient transporter	IUGR	Obesity	Type 1 diabetes	GDM
Amino acids				
System A	↓ Activity in MVM – Activity in BM	↑ Activity in MVM ↑ SNAT1 expression ↑ SNAT2 expression	↑ Activity in MVM – Activity in BM	↑ Activity in MVM – Activity in BM
System L	↓ Activity in MVM ↓ Activity in BM – Activity in MVM – Activity in BM	– Activity in MVM – Activity in BM – Activity in MVM – Activity in BM	– Activity in MVM – Activity in BM – Activity in MVM ↑ Activity in BM	↑ Activity in MVM – Activity in BM – Activity in MVM – Activity in BM
Glucose				
GLUT1	– Expression in MVM	– Expression in MVM	– Expression in MVM	↑ ↓ mRNA and protein expression dependent on maternal BMI and treatment
	– Expression in BM	↑ Expression in BM	↑ Expression in BM	
GLUT3	↑ Expression in MVM	↑ Expression in placental membranes		
GLUT4	↓ Expression in placental membranes	↑ Expression in placental membranes		
Fatty acids				
	↓ LPL activity in MVM	↑ FAT/CD36 mRNA expression in MVM	↑ EL expression	↑ LPL expression and activity
		↑ LPL expression and activity	↑ LPL activity	
			↑ FABP1, -4, -5 expression	↑ FABP1, -4, -5 expression
		↓ FATP4 expression ↓ FABP1 and FABP3 expression ↑ FATP2 expression in BM		

↑ Increase; ↓ Decrease; – No change.

Fatty acids are essential for the growth of the fetus as they are an important energy source and structural components of cell membranes. IUGR newborns have reduced subcutaneous fat depots, which may be due to decreased *de novo* fetal lipid synthesis and/or reduced placental transport of fatty acids. MVM LPL activity is reduced in preterm IUGR compared to preterm gestational age-matched controls (Magnusson *et al.*, 2004). This alteration may contribute to the reduced birth weight and minimal adipose tissue deposition observed in IUGR.

Obesity

The number of obese women of reproductive age has increased markedly in the past 30 years, paralleling the obesity “epidemic” in the general population. Maternal obesity affects both the placenta and the fetus, sometimes leading to fetal overgrowth and the subsequent delivery of large-for-gestational age or macrosomic (>4000 g) babies. Infants born to obese mothers have an increased risk of hyperinsulinaemia and hypoglycaemia in the neonatal period and are more likely to develop childhood obesity and metabolic disorders and obesity, cardiovascular, and metabolic disease in adult age. Animal models have demonstrated that the complications linked to maternal obesity in pregnancy are associated with dysregulation of placental nutrient transport (Gaccioli *et al.*, 2013).

There is a positive correlation between maternal BMI and infant birth weight, suggesting that the metabolic milieu in maternal obesity promotes placental nutrient transport. Birth weight has been positively correlated with umbilical vein glucose and insulin levels, as well as fetal hyperglycaemia. BM GLUT1 protein expression has been reported to be positively correlated to birth weight in maternal obesity however, there was no correlation in GLUT9 protein expression in ST plasma membranes and birth weight (Acosta *et al.*, 2015). An increase in the expression of BM GLUT1 is expected to increase glucose delivery to the fetus, thereby promoting fetal growth.

MVM System A activity has been shown to be increased in obese mothers delivering large babies (Jansson *et al.*, 2013). In addition, MVM protein expression of the System A isoform SNAT2 was positively correlated to early pregnancy BMI and birth weight. This suggests that upregulation of specific placental amino acid transporters may contribute to fetal overgrowth in obese women.

Placental expression of FAT/CD36 mRNA and protein and activity of the enzyme LPL are increased in pregnancies complicated by maternal obesity compared to pregnancies of normal weight women (Dube *et al.*, 2012). LPL hydrolyses triglyceride rich lipoproteins, making fatty acids available for uptake into the placenta across the MVM and activation of LPL may promote increased placental transfer of fatty acids. However, Dube and co-workers reported that maternal obesity without fetal overgrowth is associated with lower placental protein and mRNA expression of FATP4, FABP1, and lower FABP3 protein expression, and the reasons for this are unknown (Dube *et al.*, 2012). In contrast, Lager *et al.* reported BM FATP2 protein expression is increased in association to

maternal obesity (Lager et al., 2016). Although the precise role of placental fatty acid transporters in maternal-fetal lipid transport remains to be established, increases fatty acid transporter expression in pregnancies complicated by maternal obesity may lead to an enhanced transfer of fatty acids to the fetus.

Diabetes

The number of women with diabetes in pregnancy is increasing globally. Gestational diabetes mellitus (GDM), which makes up the majority of diabetes cases in pregnancy, and type 1 diabetes both lead to increased risk of perinatal morbidity and mortality, and are associated with a susceptibility to develop diabetes and GDM later in life. Maternal hyperglycaemia and hyperinsulinaemia are associated with fetal overgrowth and often large for gestational age babies, increasing the risk of delivery complications and birth injury. Accelerated fetal growth is believed to be caused by maternal hyperglycaemia, which results in increased fetal glucose levels, stimulating fetal insulin production. Insulin is the major growth hormone in fetal life; therefore increases in fetal insulin can lead to accelerated fetal growth. However, birth weight is not positively correlated with maternal glucose levels in type 1 diabetes or GDM, suggesting that there are other contributing factors leading to fetal overgrowth. An increased fetal availability of other nutrients than glucose, including fatty acids, and amino acids, which are potent stimulators of insulin, may promote fetal growth in pregnancies complicated by maternal diabetes.

In type 1 diabetes system A, but not system L, activity is increased in the MVM of the ST, consistent with an increased capacity of the ST to transfer amino acids to the fetus (Jansson et al., 2002). Type 1 diabetes is also associated with an increase in GLUT1 protein expression and glucose uptake in the BM (Jansson et al., 1999). Birth weight is positively correlated with GLUT1 expression in the BM from placentas of type 1 diabetics. As the BM acts as the rate-limiting step in glucose transport in the ST, an increase in expression and activity of glucose transport at this membrane could lead to an increase in the delivery of glucose to the fetus. Infants of mothers with diabetes have increased fat mass, which may be due to an increased de novo fetal lipid synthesis from glucose or be caused by an increase in lipid transport from the mother to the fetus. Consistent with the latter hypothesis, placental triglyceride concentrations, EL gene expression and LPL activity have been reported to be increased in type 1 diabetes (Lindegaard et al., 2006; Magnusson et al., 2004). Moreover, FABP protein expression in placentas from women with type 1 diabetes is also increased (Magnusson et al., 2004; Radaelli et al., 2009). This suggests that in type 1 diabetes there is an increase in lipid uptake and transport by the placenta, contributing to the increased fetal body fat mass in these infants.

The available data on placental nutrient transport in GDM is inconsistent, possibly due to the limited number of study subjects included in most studies and the lack of full consideration of a range of cofounders including the influence of diverse treatment regimens and maternal obesity. In nonobese women with insulin-controlled GDM, placental GLUT1 mRNA and protein expression was increased and GLUT4 mRNA and protein expression was decreased compared to nonobese diet controlled GDM women. In obese women with insulin-controlled GDM placental GLUT4 mRNA expression was lower than obese women with diet controlled GDM. These observations highlight that maternal BMI and the mode of treatment for GDM are associated with differences in the pathophysiology of this disease (Colomiere et al., 2009). System A activity is upregulated in the MVM in women with GDM with or without LGA babies when compared to healthy controls, whereas in healthy women with LGA babies system A activity in the MVM was unaltered. This suggests that there is an increased uptake of neutral amino acids into the ST, allowing for an increased delivery to the fetus. System L activity is also increased in the MVM in GDM pregnancies with LGA babies, whereas there is no change in system L activity in type 1 diabetes with LGA. As in type 1 diabetes, there is an upregulation of placental FABP protein expression in GDM (Magnusson et al., 2004; Radaelli et al., 2009). In term placentas from normal weight women or overweight/obese women with GDM, LPL expression, and activity are increased compared to normal controls (Dube et al., 2012). However, in a study that of insulin-treated GDM women only, LPL expression was downregulated (Radaelli et al., 2009). Dysregulation of placental lipid transport and metabolism, regardless of maternal BMI and GDM treatment, are thought to be playing a key role in the fetal fat accumulation and LGA babies that are more frequent in GDM pregnancies.

Glossary

Allogeneic In transplantation biology, this term refers to tissues transplanted within the same species but between genetically dissimilar donor and recipient. This dissimilarity introduces donor *alloantigens* into the host, and therefore is recognized as foreign by the host immune system. This is in contrast to *syngeneic* grafts, which are genetically identical to that of the host and therefore are not rejected.

Blood group antigens Antigens found mainly on the surface of blood cells that are capable of being recognized as foreign by the immune system. In humans, there are different blood group systems; in most cases, the antigenic residue resides within carbohydrate residues of proteins or lipids. Blood group antigen systems include Rhesus, ABO, and Kell antigens.

Clonal expansion Rapid replication of a lymphocyte after its encounter with cognate antigen that gives rise to multiple progeny with the same antigen specificity.

Complement A group of evolutionarily conserved serum proteins of the innate immune system that is activated in a cascade manner, whose products act to promote phagocytosis, enhance inflammation, and to eliminate pathogens by forming pores on the pathogen membrane surface.

Costimulatory molecule Membrane proteins (B7 and CD40) that are expressed on the surface of activated antigen presenting cells that provide a required second signal for T cell activation; the first stimulatory signal comes from MHC-T cell receptor ligation.

Cross presentation Process by which dendritic cells internalize and degrade extracellular proteins or pathogens, and shuttle resulting peptide antigens to the MHC class I molecules for cell surface presentation. This is a specialized function of dendritic cells that other cells have only limited capacity to perform.

Decidualization A highly specialized differentiation response to implantation of the conceptus, in which endometrial stromal cells transform into enlarged hormone-producing cells that will ultimately surround the implanted embryo.

Effector lymphocytes Activated T and B cells following expansion and differentiation in response to pathogen, and that have gained ability to promote pathogen clearance. Different subsets of lymphocytes have different effector functions. T helper cells are the earliest to respond to pathogen in an adaptive immune response, not only because they can respond to antigen presented by professional antigen presenting cells, such as dendritic cells, but also because they produce the required “help” to other lymphocytes. This help occurs in the form of cytokines that are needed for differentiation of either cytotoxic T cells or B cells that recognize antigens related to that of the T helper cell. Whether cytokine help is provided to cytotoxic T cells or B cells depends on the type of antigen/pathogen as well as the surrounding environment. The effector function of cytotoxic T cells is to kill infected target cells, while the effector function of activated B cells, or plasma cells, is to produce antibodies, which in turn neutralize toxin, kill pathogens, or stimulate complement-mediated cytotoxicity.

Extracellular vesicles There are three broad classes of extracellular vesicles that differ according to their origin, size and molecular contents. Exosomes are the smallest of these, ranging 50–150 nm in diameter. These vesicles arise from the inward budding of the limiting membrane of late endosomes, which form intraluminal vesicles (ILV). Subsequent fusion of the endosome with the plasma membrane causes release of the ILV. Larger microvesicles (MV), which arise from budding of the plasma membrane, represent the second class, ranging from 50 to 1000 nm. Finally, apoptotic bodies arise from the blebbing cell membranes of cells undergoing programmed cell death. The anatomy of the outer syncytiotrophoblast layer of placenta and its direct contact with maternal blood allows for placental vesicle release into the blood and interaction with the maternal immune system.

Haplotype A group of linked allelic genes that is inherited as a unit from a parent. For example, humans have multiple polymorphic HLA genes, and they inherit two sets, or haplotypes, of these genes, one from each parent; this is similarly true for KIR genes. One KIR haplotype is designated *A*, and another haplotype *B*, then a person may have a combined haplotype of *KIRAA*, *AB*, or *BB*.

Homograft Tissue transplanted from a donor to a recipient of the same species. This is in contrast to *xenograft*, which is tissue transplanted from a donor to a recipient of a different species. A homograft can be either *allogeneic* (between genetically different individuals) or *syngeneic* (between genetically identical individuals, such as between identical twins or mice of the same strain). Xenografts are always allogeneic.

Killer inhibitory receptors Polyallelic transmembrane receptors present on the surface of natural killer cells, whose ligands are class Ia and class Ib MHC molecules. Ligation of KIR by MHC can inhibit the cytotoxic function of NK cells, or, in uterine NK cells, promote cytokine function.

Major histocompatibility complex (MHC) A group of genes that encode cell surface proteins responsible for mediating recognition of endogenous and exogenous peptides by the T lymphocytes. In humans, MHC molecules called human leukocyte antigens (HLA); thus the two terms are synonymous. MHC class I molecules are expressed on nearly all cells, and

present peptides derived from intracellular proteins; this group can be further broken down into MHC class Ia (classical) and MHC class Ib (nonclassical) molecules. Class Ia MHC molecules are expressed by nearly all nucleated cells, with notable of red blood cells and placental trophoblast cells. These proteins are highly polymorphic and function primarily to present pathogen-derived peptides to cytotoxic T cells the T cell receptor. Dendritic cells also use class Ia proteins to present peptides from extracellular material and pathogens, using a process called *cross-presentation*. Class Ib molecules have limited polymorphism, are expressed by trophoblast cells, and serve as ligands for activating and/or inhibitory receptors on innate and adaptive immune cells. MHC class II molecules are expressed primarily by antigen presenting cells and display peptides derived from extracellular material to helper T cells.

Minor histocompatibility antigen Antigenic peptides derived from proteins of polyallelic genes that can be presented by MHC class I and/or II molecules. Allelic differences can arise as single nucleotide polymorphisms, insertions, deletions, or coding on the Y chromosome. These antigens can be responsible for chronic rejection of transplants, even when tissues are matched for class I and class II MHC. An example of a minor antigen is the SMCY antigen, which derives from a gene encoded on the Y chromosome. While an X homolog of this gene exists (SMCX), differences in amino acid sequence of the Y-encoded allele of the gene gives rise to several class I and class II-restricted peptide antigens. Since females lack SMCY, their T cells will recognize the protein as foreign, provided that they possess the appropriate MHC.

Naïve T cells Mature T lymphocytes that have not encountered cognate antigen and have the potential to become activated once stimulated by antigen presenting cells.

Regulatory T cells A subpopulation of T cells that maintains tolerance to antigens derived from self-proteins. These cells are critical for preventing autoimmune disease. Regulatory T cells can be formed during T cell development in the thymus, or can be induced from mature T cells in the periphery. In pregnancy, it is the latter type that is thought to be critical for maternal tolerance to the fetus.

Uterine natural killer cells These cells are related to classical natural killer cells, which serve in the innate immune system to target and kill virally infected cells. Uterine natural killer cells, however, exhibit a different immunophenotype, and can be identified by their high level of CD56 and absent expression of CD16; classical NK cells are double positive for CD56 and CD16. Uterine NK cells use killer inhibitory receptors (KIR) to bind class Ib MHC molecules on trophoblast cells and enhance production of proangiogenic cytokines. Uterine NK cells constitute about 40% of total cells, 70% of leukocytes in the decidua; thus, their importance has long been regarded as high.

Introduction

Pregnancy is often compared to an *allogeneic* or semiallogeneic graft because of paternal genetic contribution, which is immunologically distinct from the mother, to the fetus. In 1953, Sir Peter Medawar, a zoologist at the University of Oxford during World War II, was recruited to help solve the problem of failing skin grafts on account of victims of the war. Having only uncertain prior experimental evidence of others to go on, Medawar performed a series of experiments that confirmed *homograft* rejection as an immunological event. In doing so, he became the preeminent leader in the field, receiving the Nobel Prize for his work in 1960.

Medawar's musings famously included the question of how the fetus survives in utero despite its allogeneicity in relation to the mother (Medawar, 1953). From the viewpoint of transplantation, the genetically distinct fetus should elicit an immune rejection response, but yet develops unhindered during normal pregnancy. Since then, studies have improved our understanding of maternal immune adaptation to pregnancy. Here, we review the immunological events that occur in pregnant women, placing this into context with the innate and adaptive immune responses to infection and transplantation (Table 1). Particular attention is paid

Table 1 Spectrum of immune responses to self and non-self

Immune response to	Self	Autograft	Pregnancy	Self: injury	Self: autoimmune disease	Allograft	Pathogen
Source of antigens	None	None	Paternal alloantigens	None	Self cells and tissues	Alloantigens	Pathogen antigens
Degree of difference from self	None	None	Semi-foreign	None	None	Foreign	Foreign
Initial tissue damage	No	Yes	Minimal/controlled	Yes	Possible	Yes	Yes
Danger signals	No	DAMPs	Possible in abnormal pregnancy	Injury: DAMPs	Possible DAMPs	DAMPs	PAMPs
Type of immune response	None	None	Innate and Adaptive	Innate	Innate and Adaptive	Innate and Adaptive	Innate and Adaptive
Immune outcome	Tolerance	Tolerance	Tolerance	Wound healing	Rejection	Rejection	Clearance

Different sources of self and foreign antigens elicit different types of immune responses, which can be explained at least partially by the source of antigens and presence of tissue damage and danger. The *green-red bar* indicates severity of immune response, starting from tolerance (*green*) to full immunity and clearance (*red*).

to the means by which each elicits the immune system, and why foreign organisms and transplanted tissue incite immunity, whereas the fetus also establishes both tolerance and collaboration with maternal immune cells to promote placentation and fetal growth.

Overview of Innate and Adaptive Immunity

The cells of the immune system, collectively called leukocytes, can be classified into the innate and adaptive branches. Some leukocytes functionally bridge these two arms by responding to innate signals and in turn, activating the adaptive cells. Innate immune cells include macrophages, neutrophils, eosinophils, basophils, and mast cells. Macrophages and neutrophils specialize in ingestion (phagocytosis) and destruction of foreign organisms. The innate immune system is more ancient than adaptive immunity, and as such, their response is limited in diversity and specificity. Nonetheless, they home to damaged tissues very rapidly whether or not pathogens are present. Further, they arrive armed with presynthesized, ready to be released effector molecules. The lifespan of innate immune cells is short: once they have discharged their defenses, the cells die.

The adaptive immune system, in contrast, is governed by T and B lymphocytes and is slower to respond because it requires days for cells to proliferate and differentiate prior to effecting their function. Proliferation by *clonal expansion* is necessary because they sense pathogens through receptors that are highly specific to discrete pathogen-specific antigens, and lymphocytes of individual antigenic specificity (clonality) circulate at exceedingly low numbers. Antigenic stimulation, together with the necessary *costimulation*, causes antigen-specific lymphocytes expand many-fold and differentiate into *effector lymphocytes*, which are then ready to eliminate pathogen. The low frequency of individual lymphocyte clones, as well as the manner in which their antigen receptors recombine during lymphocyte development, permits an extraordinary range of lymphocyte diversity within the circulation. Thus, the adaptive immune system is able to canvas the body for an enormous array of pathogens simultaneously. Effector T and B cells are short-lived; however, unlike cells of innate immunity, they retain “memory”: after responding to their antigen, T and B cells form daughter cells that mount stronger, faster recall responses upon re-encounter with the same antigen, curbing or preventing recurrent disease with the same pathogen.

Bridging the adaptive and innate immune systems are dendritic cells (DC). These cells employ multiple mechanisms of ingestion (phagocytosis, pinocytosis, and macropinocytosis), and in their immature state, sample their environment continuously. Dendritic cells can sense the presence of pathogens, and respond vigorously to pathogenic stimuli. The mechanisms of degradation and processing of ingested products is highly specialized and designed to relay information about the products to the adaptive immune system. In this way, DC are uniquely able to prime *naïve T cells*, thus initiating an immune response.

Self, Non-Self, and Danger

To understand the nature of the maternal immune system’s response to the semi-allogeneic fetus, it is helpful to have an understanding of how it responds to both pathogens and to transplanted tissue. Fundamentally, the immune system’s mission is to defend the body from organisms that cause disease. Although this task can be further reduced conceptually as defense against anything that is non-self, in reality, it is only when harm or danger is imminent that the immune system needs to deploy its defenses (Fig. 1). It is thus imperative that mechanisms be in place by which both *foreignness* and *imminent damage* are identified (Matzinger, 2002). Clearly, the immune system should leave normal-self alone at minimum, as it should certain foreigners like the fetus and, ideally, transplanted organs. At best, it should promote the establishment and growth of self, the fetus, and transplants.

On the surface, the early events of infection, transplantation, and pregnancy parallel each other, in that all involve entry of a foreigner past a first line of immune defense (e.g., an epithelium) (Table 1). Upon breach of this barrier, immune cells must immediately determine whether or not danger is imminent. To this end, the cells employ pattern recognition receptors (PRR), which are cell surface-associated or intracellular receptors whose ligands derive from damaged cells, pathogens, or both. Damaged cells release danger signals known as DAMPs (danger-associated molecular patterns); these are molecules that normally reside and function intracellularly, but whose extracellular release alerts immune cells that damage has been done. DAMPs include high-mobility group box 1 (HMBG1), heat shock proteins (HSPs), and low-density lipoprotein (LDL). In the absence of pathogens, a DAMP-initiated inflammatory response normally resolves; exceptions may occur in cases of autoimmune disease.

Fig. 1 Self, non-self, and harm. At the most basic level, the function of the immune system can be distilled down to recognition of self vs. non-self (light blue, light yellow). Critically, the immune system must also be able to sense harm, or imminent danger. Thus, some “self” can be harmful (cancer), and some non-self, harmless (fetus). The immune system distinguishes harmful and harmless through its use of pattern recognition receptors. Adapted from Matzinger, P. (2002). The danger model: A renewed sense of self. *Annual Review of Immunology*, 12, 991–1045.

If pathogenic organism(s) are also introduced, on the other hand, pathogen-derived danger signals (PAMPs) assume a pivotal role. PAMPs are not highly specific to different pathogens, but instead are evolutionarily conserved such that the same leukocyte-associated PRR can recognize many different pathogens. Examples include lipopolysaccharide (LPS) of Gram-negative bacteria, lipoteichoic acid of Gram-positive bacteria, and double-stranded RNA of certain viruses. PAMPs induce strong inflammatory responses, and importantly, vertebrate cells lack these molecules. Thus, the interaction of PAMPs with PRRs alerts immune cells to the presence of both foreignness and danger.

At this stage, DC assume a pivotal role. Ligand of PRRs by PAMPs or DAMPs on DC induces dramatic changes that result in “maturation” of the cells, which involves down-regulation of phagocytosis and upregulation of *major histocompatibility complex* (MHC) and costimulatory molecules, *antigen presentation*, and subsequent stimulation of T cells. Antigen presentation involves the partial degradation of protein antigens creating peptides that are then complexed with MHC and presented to T cells. When T helper cells recognize peptide through its T cell receptor (TCR), together with appropriate costimulation from DC, they respond by clonal expansion and cytokine production, in turn activating cytotoxic T and/or B cells for killing activity and antibody production, respectively. Altogether, at least three signals are required to produce T lymphocyte priming and activation: the “danger” signal provided through PRR, MHC/foreign peptide ligand of TCR, and costimulation. Absent any one of these, inflammation will resolve, and antigen-specific tolerance will ensue.

Immune Response in Transplantation

With an understanding of how pathogens activate immunity, we can now consider a situation closer in analogy to the fetus, that is, a transplanted organ. Tissue and organ grafting is performed for the patients *benefit*, so why is graft rejection such a problem, and what molecular mechanisms account for graft rejections? Which of these mechanisms could be problematic for pregnancy?

Even with the best available surgical technique, transplantation iatrogenically induces tissue damage associated with excision—that is, removal of an organ and consequent ischemia/reperfusion and cell death. Because of this, transplanted tissues release extensive amounts of DAMPs, providing an abundance of the signals that induce maturation of both host and donor DC. If the patient receives his/her own tissue of that of an identical twin, and assuming the absence of pathogens, no foreign material is introduced, inflammation resolves, and the tissue heals and is accepted. However, if the donor tissue derives from an allogeneic individual, many foreign proteins are introduced. The presence of both danger signals associated with the surgical process and foreign antigens cause the immune system to “mistake” the transplanted tissue as dangerous, setting the stage for activation of an adaptive immune response and allograft rejection.

The nature of the rejection response depends what types of mismatched antigens occur between donor and recipient. For example, if ABO *blood group antigens* are not correctly matched between donor and recipient, preexisting antibodies (produced because of prior exposure to similar antigens associated with plants, viruses, and bacteria), together with *complement*, can cause hyperacute graft rejection, which takes place within only minutes of transplantation. Because of the dangers of hyperacute rejection, matching of blood group antigens is mandatory in tissue transplantation.

The next major barrier to graft acceptance is differences in the highly polymorphic MHC molecules between donor and recipient. A large proportion—1%–10%—of mature T cells in a given person or animal cross react to foreign (allogeneic) MHC molecules. Though the molecular basis for this alloreactivity is not well understood, it is a major clinical problem in transplantation, causing acute rejection of transplanted organs over days or weeks. Because of this, “tissue typing,” or matching of MHC allotypes between donor and recipient, is also indispensable for successful transplantation. In humans, six MHC molecules are typed for in the clinic: three class I molecules, human leukocyte antigen (HLA)-A, HLA-B, HLA-C; and three class II molecules: HLA-DP, HLA-DQ, and HLA-DR. Although matching for all six antigens often proves a significant challenge, the relatively low number makes it feasible.

The last immunological hurdle to successful transplantation, is more difficult to overcome and involves differences in *minor histocompatibility antigens* between donor and recipient. Minor antigens derive from normal cellular proteins, and can elicit antigenicity because of allelic differences between individuals. Since T cells cannot sense antigenic proteins directly, minor antigens are presented in the context of class I and/or class II MHC molecules, similar to pathogens. In transplantation, donor DC that accompany the graft can present minor antigens directly; if the antigen is lacking and thus foreign to the recipient, they will be recognized in a T cell-dependent, MHC-restricted manner. Alternatively, donor minor antigens can be *cross-presented* by recipient DC. T cells There are more than 60 known minor antigens, and likely hundreds or even thousands more are yet undiscovered—far too many to match in the clinic. Although lymphocyte reactions to minor antigens are generally weaker and slower than those against MHC, they are responsible for chronic rejection of grafts, often necessitating long-term immunosuppressant drug treatment of recipients.

Pregnancy: Invasion, Damage, and Antigens

How do each of these components of immune activation and transplant rejection relate to pregnancy? During implantation and placental development, pregnancy too, involves breach of an epithelial barrier, production of inflammatory signals, and introduction of foreign antigen. However, the maternal immune and reproductive systems together with the fetal–placental unit employ extensive strategies to ensure robust tolerance to gestational antigens. Unlike the events of transplantation and infection, which involve immunity-driven clearance of foreign material, the immunological events of normal pregnancy support implantation, placentation, and tolerance to fetal antigen.

Coitus. From the start, the maternal immune reaction in pregnancy differs from that of microbes and transplants. In men, anti-sperm antibodies that negatively impact fertility can be elicited as a result of vasectomy, injury, or infection to the genital tract. Immunity to sperm occurs in 1%–2% of women, but interferes with fertility only rarely. Key differences include danger signals and location: leakage of sperm, together with DAMPs into the blood in men, as opposed to lack of DAMPs and deposition of sperm and seminal fluid into the vaginal canal and cervix in women.

Coitus induces an inflammatory reaction in the cervix, an event that not only represents the first introduction of paternal antigens into the female reproductive tract, but also the incipient events of immune tolerance to gestational antigens (Robertson and Sharkey, 2016). Studies first performed in mice and later confirmed in women demonstrated that coitus induces neutrophil, macrophage, and DC accumulation, as well as production of proinflammatory cytokines and chemokines. Neutrophils ingest excess sperm, microbes, and debris. Seminal fluid, independently of sperm or the physical act of coitus, is responsible for the inflammatory reaction, mediated by bioactive factors including prostaglandins, growth factors, and cytokines.

Although sperm lacks MHC molecules, other cellular and soluble seminal fluid constituents contain both MHC and minor antigens. Seminal fluid antigens enter the vaginal, cervical, and endometrial mucosa, where they are presented by local DC. This early reaction primes maternal T cells, and may culminate in generation of *regulatory T cells* (T_{Reg}), which vitally contribute to fetal–maternal tolerance (Moldenhauer et al., 2009; Aluvihare et al., 2004). Indeed, several studies show that repeated exposure to seminal fluid, even in the absence of pregnancy, protects against preeclampsia—a phenomenon that may be explained by additive tolerogenic effects of seminal fluid in women. Clearly, neither exposure to seminal fluid nor the associated inflammatory response is required for pregnancy, but data suggest improved pregnancy outcome with seminal fluid exposure, for example, when couples engage in intercourse around the time of in vitro fertilization. Thus, while an immune response to sperm or seminal fluid can sometimes occur, the sequence of events at the inception of pregnancy ensure tolerization rather than immunization.

Implantation: Breach of the uterine epithelial barrier. Once fertilization occurs and a blastocyst has formed, the semi-foreign embryo is positioned for implantation. At the blastocyst stage, embryonic trophoblast cells attach to and invade the endometrium, breaching the epithelium and eliciting prostaglandins, leukotrienes, histamines, cytokines, and chemokines, and vascular leakage—in other words, inflammation. However, the ensuing response is atypical: together with prerequisite hormonal priming of the uterus, the implanting embryo triggers *decidualization*. Remarkably, the similarity of implantation to wound induction is such that “artificial” decidualization in the absence of an embryo can be stimulated by mild mechanical abrasion or “scratching” of the endometrium in an experimental setting in mice; endometrial scratching may improve uterine receptivity in some women undergoing assisted reproduction. Although maternal endometrial cells die in the process of implantation, they do so via apoptosis and local macrophages rapidly clear the dead cells. Thus, cellular damage, danger signals, and DAMPs are kept to a minimum.

While macrophages and T cells are present in steady numbers prior to and during decidualization, a unique population of granular leukocytes called *uterine natural killer* (uNK) cells proliferate to high numbers during decidualization. Animal studies have shown that both decidualization and pregnancy will proceed in the absence of these cells; however, establishment of the maternal blood supply to the placenta, often referred to as spiral artery remodeling, is impaired (Zhang et al., 2011). Uterine NK cells encircle spiral arteries prior to their transformation in the first trimester of gestation, and help modify the arteries by secreting angiogenic factors, cytokines, and chemokines, and recruiting trophoblast cells towards the vessels they will ultimately line. A unique feature of hemochorial placentation, vascular remodeling coincides with completion of placental maturation, in time for commencement of rapid fetal growth. Failure of remodeling is associated with several pathologies of pregnancy, including preeclampsia and fetal intrauterine growth restriction.

Immature DC are also present in the developing decidua. Although these cells can be activated in vivo, and potently present antigen in vitro, they appear not to do so effectively in vivo (Collins et al., 2009). Instead, uterine DC play an important role in decidualization. Without DC, pregnancy fails around the time of implantation due defective decidualization (Plaks et al., 2008). Thus, like uterine NK cells, uterine DC have unique and indispensable functions in pregnancy.

Intertwined with the process of maternal spiral artery remodeling is invasion of trophoblast cells. As the blastocyst encases itself within the decidua, its trophoblast cells give rise to the major placental trophoblast cell populations that define the physical, and therefore, immunological boundaries between the mother and fetus. Invasive extravillous trophoblast cells reside in close juxtaposition with a plethora of maternal immune cells, participating with uNK cells to achieve spiral artery remodeling. A second population, the syncytiotrophoblast, which will ultimately constitute the outermost layer of the chorionic villi in the mature placenta, is bathed in maternal blood starting around 13 weeks (i.e., upon establishment of maternal blood supply to the placenta), and throughout the remainder of gestation. The syncytiotrophoblast consists of a continuous multinucleated layer covering the entire placental surface. The syncytiotrophoblast–maternal blood interface is enormous, covering as much as 12 m² at term (Benirschke and Kaufmann, 2000).

One of Medawar’s postulates as to why the semiallogeneic fetus is not rejected by the maternal immune system was that the fetus is physically separated from the mother. This is partially correct, as the trophoblast serves as an epithelial barrier separating mother and fetus. Importantly, however, paternally derived “foreign” antigens are expressed by both the fetus and the placenta, including the border trophoblast populations. Furthermore, trophoblast cells release an abundance of *extracellular vesicles* directly into the maternal blood—potentially expanding the area of maternal–fetal contact exponentially as these vesicles circulate throughout the mother’s body. Collectively, this intimate maternal–fetal contact raises important, poorly understood questions of how the same proteins that are of significance in transplantation, exposed and released in such abundance from the placenta, are dealt with in pregnancy.

Blood group antigens. Blood group antigens are a significant clinical concern in pregnancy. Because AB antigens are minimally expressed by fetal erythrocytes, disease caused by these antigens is rare. However, the RhD antigen is of importance in cases of

an RhD-positive father and an RhD-negative mother. Here, the fetus may inherit the antigen and prime the mother's immune system, especially at birth, when the placenta hemorrhages during separation from the uterine wall. Then, the mother can be immunized by fetal RhD, forming cytotoxic IgG antibodies. While this may not be an issue for the first pregnancy, subsequent pregnancies with RhD-positive fetuses are at significant risk for hemolytic disease of the newborn—a condition analogous to antibody-mediated graft rejection. Fortunately, preventative treatment with Rho(D) immune globulin is effective.

MHC. At first glance, the paternally inherited MHC might seem problematic, particularly as the placenta is continually exposed to maternal immune cells. However, syncytiotrophoblast cells strictly regulate MHC expression, repressing all polymorphic class I and class II MHC. This precludes trophoblast cells from becoming targets of alloreactive maternal T cells. Some women generate antibodies against paternal MHC during pregnancy, possibly due to passage of fetal (MHC-expressing) cells into the mother. Still, these anti-fetal MHC antibodies appear to be innocuous.

Invasive extravillous trophoblast cells in the decidua express only certain MHC molecules: the non-polymorphic class Ib molecules, HLA-E, -F, and -G, and the class Ia molecule, HLA-C. These molecules serve as ligands for receptors on uterine NK cells. Specifically, HLA-E is a ligand for the inhibitory receptor, CD94/NKG2A, a receptor expressed on a subset of uNK cells that inhibits NK cell cytotoxicity, possibly protecting trophoblast cells in this respect (King et al., 2000). Little is known about the function of HLA-F, but this protein may also serve as a ligand for uNK cells.

HLA-G is uniquely expressed on extravillous trophoblast cells. Alternative splicing of HLA-G mRNA generates surface-bound (HLA-G1–4) and soluble (HLA-G5–7) isoforms, which have differential abilities to interact with its receptors: the NK and CD8 T cell inhibitory receptor LILRB1, the inhibitory monocytes receptor LILRB2, and the activating NK receptor KIR2DL4. HLA-G plays a role in maternal-fetal tolerance due to its ability to inhibit T cell proliferation and cytotoxicity and inhibit maturation of DC (Hunt et al., 2005). Its action on NK cells, on the other hand, may stimulate production of pro-angiogenic factors and thus may play role in spiral artery remodeling (Rajagopalan and Long, 2012).

HLA-C has a complex but important relationship with uNK cells. HLA-C is more polymorphic than the non-classical HLAs, having hundreds of alleles. This may have functional implications in terms of T cells that home to the maternal-fetal interface; additionally, HLA-C may be important in pathogen defense by presentation of pathogen antigens.

Uterine NK cells also interact with HLA-C. There are two functional groups of HLA-C alleles, HLA-C1 and HLA-C2, distinguished by the identities of two amino acids at positions 77 and 80, and which differ in utilization of *killer inhibitory receptors* (KIR). KIR are also polymorphic, and the combination of HLA-C and KIR *haplotypes* expressed by fetal trophoblast cells and maternal uNK cells, respectively, likely determines the balance of activating and inhibitory signals the uNK cell receives from the trophoblast, and in turn, how the uNK cells function. Genetic association studies have shown that an overall balance towards activating HLA-C and KIR haplotypes favor successful pregnancy outcomes, while inhibitory haplotypes predispose women to pregnancy disorders (Parham and Guethlein, 2010). Functionally, the activated uNK phenotype is hypothesized to drive these cells towards secretion of trophic and pro-angiogenic growth factors, chemokines, and cytokines. The inhibitory phenotype, in contrast, may constrain these progestational functions, and may disfavor angiogenesis and spiral artery remodeling.

Minor histocompatibility antigens. Minor antigens include “male” antigens encoded on the Y chromosome and others that are autosomally encoded. Unlike MHC molecules, many minor antigens are highly expressed by placental trophoblast cells (Holland et al., 2012). Further, they are cross-presented by maternal antigen presenting cells in much the same way as transplanted tissue antigens are by recipient DC (Erlebacher et al., 2007). Antigens gain access to maternal antigen presenting cells in lymphoid organs as they are released from the placenta into the maternal circulation, either as free or as vesicle-associated proteins. This allows priming of maternal T cells, which persist as memory cells *in vivo* for many years following pregnancy (James et al., 2003; van Halteren et al., 2009).

Despite the ability of T cells to respond to fetal antigen, the expansion of these T cells is blunted. They do not gain full effector function, neither killing fetal cells nor promoting production of cytotoxic antibodies. This is likely explained a number of factors, perhaps most importantly, including a lack of danger signals/DAMPs and thus lack of DC maturation (Bonney and Matzinger, 1998); expansion of regulatory T (T_{Reg}) cells during pregnancy; and lack of T cell access to the maternal-fetal interface due to epigenetic silencing of decidual chemokine genes (Nancy et al., 2012). Possibly, the manner in which fetal antigens are presented during pregnancy also contribute to the blunted response, but little is known about this potential mechanism.

Critical Factors in Preventing Maternal Immune Attack of the Fetus

Although there are a number of clinical syndromes, such as preterm birth and preeclampsia, that have immunological components, these involve inflammation rather than fetal antigen-specific lymphocytes. Despite some claims and/or loose usage of terminology, evidence that these syndromes represent “fetal allograft rejection” is sparse. A classical scientific approach to determining whether a factor is critical for a physiological/pathological process is ablation/replacement; this approach has been used in reproductive immunology, and occasionally, reports of “essential mediators” of maternal-fetal tolerance are reported. However, these reports are rarely upheld, probably because of robust and redundant mechanisms of tolerance.

A notable exception appears to be the requirement for regulatory T cells for maternal-fetal tolerance, as alluded to in preceding sections. This was first shown in an elegant study in which lymphocyte-deficient pregnant mice were reconstituted with either a complete complement of T cells, or with all T cells except T_{Reg} cells (Aluvihare et al., 2004). Here, the authors observed mid-gestation fetal loss in allogeneic, but not syngeneic pregnancies, suggesting that fetal loss is related to expression of paternally-inherited alloantigens. T_{Reg} cells in pregnancy expand due to both hormone- and antigen-dependent mechanisms;

moreover, during subsequent pregnancies, antigen-specific T_{Reg} cells expand more rapidly and to a greater degree than in first pregnancies, suggesting that these cells, like conventional T cells, possess memory (Rosenblum et al., 2016). T_{Reg} cells also expand during pregnancy in women, and reduced expansion is associated with adverse pregnancy outcome. While a number of studies have confirmed that T_{Reg} are critical for pregnancy, little is known about their mechanism of action; important open questions include which effector cells are controlled by pregnancy-induced T_{Reg}, and whether antigen-specificity and/or cell–cell contact is required for T_{Reg} function during pregnancy.

Summary and Future Directions

Key differences exist between a transplanted organ and the fetus during pregnancy that help explain Medawar's original question of how the fetus evades maternal immune rejection. Differences in introduction and establishment of embryonic and fetal growth in ways that avoid generation of "danger" signals, promote generation of suppressive T_{Reg} cells, and preclude access of dangerous lymphocytes to the maternal–fetal interface are likely essential. The past 60 or more years has seen leaps forward in our understanding of the biology of pregnancy and immunology, yet many important questions remain unanswered. The contributions of the immune system to pathologies of pregnancy remain enigmatic, and the insight to apply our knowledge in the clinic is of paramount importance.

Looking forward, we can bring the lessons of the past decades of research together with emerging questions, while taking advantage of the newest technical advances. For example, recent work has raised much interest in the role of placental extracellular vesicles and cell-free fetal DNA in modulating the maternal immune system. Already abundant in maternal blood in normal pregnancy, placental vesicles are even more copious in abnormal pregnancy, contain altered cargo, and differentially affect target cells. Our understanding of the role of these cells in modulating innate and adaptive immune cells in normal pregnancy is in its infancy, as is how they may affect disease. The discovery of cell-free fetal DNA has seen rapid translation as a clinical tool for noninvasive prenatal testing; however, like extracellular vesicles, their role in maternal biology and immunology is poorly understood.

There also exist a number of well-documented but poorly understood phenomena. For example, B cells, the precursors to antibody-producing plasma cells, are dramatically altered in pregnancy as evidenced by pregnancy-associated shrinkage of the bone marrow (where B cells develop), changes in B cell surface markers, and shifts in antibody production. Similarly, the thymus, where T cells develop, undergoes dramatic hormone-mediated changes during pregnancy, but there are almost no explanations of its importance.

It is likely that the solutions to these and other hanging questions will bring great insight into how the maternal immune system responds to the fetus in pregnancy. Continued collaboration between basic and clinical scientists will bring answers, and more importantly, novel strategies to manage clinical problems of not only pregnancy, but also diseases with immunological components such as autoimmune disease, tissue and organ transplantation, and cancer.

Yolk Sac

Daoyin Dong and Peixin Yang, University of Maryland School of Medicine, Baltimore, MD, United States

Introduction

The yolk sac is the first fetal membrane to be formed in all mammals and is the oldest of the extra-embryonic membranes. It is a bilayer structure of mesoderm- and endoderm-derived cell layers. The human embryo retains a yolk sac, which goes through primary and secondary phases of development. Human yolk sac has been considered to be a vestigial organ at the beginning of its formation, an evolutionary remnant based on the fact that it does not contain any yolk. Later in development, yolk sac has been shown to deliver nutrients, immunoglobulins and oxygen to the embryo due to an absence of maternal intervillous circulation in the first 12 weeks of pregnancy (Exalto, 1995). Currently, yolk sac is suggested to contribute to erythropoiesis, hematopoiesis, vasculogenesis and subsequently organogenesis. Recent studies demonstrate the role of yolk sac in diabetic vasculopathy, which is associated with maternal diabetes-induced birth defects.

Yolk Sac Development

The development and destiny of the yolk sac vary greatly across mammals and developmental stages, even within the same species (Carter, 2016). There are three different principal patterns of yolk sac development (Carter and Enders, 2016). In the first, yolk sac is used to support the early embryo in gestation. A vascular yolk sac is attached to the chorion, named choriovitelline placentation. Subsequently, the yolk sac is removed from the chorion by expansion of the exocoelom and allantois, and fetal development is supported by choriovitelline placentation. This occurs in pigs, horses and many other mammals (Carter, 2016; Carter and Enders, 2016).

The second pattern of yolk sac development is typical in rodents, insectivores, and lagomorphs. At the blastocyst stage, the extra-embryonic endoderm appears. Following blastocyst attachment, endoderm cells migrate around the inner surface of the trophoblast and the blastocyst cavity becomes the primary yolk sac. Trophoblast everts the epiblast into the yolk sac cavity by proliferation to form the ectoplacental cone. The space at the centre of the epiblast is called pro-amnion (Fig. 1). It will divide into the ectoplacental cavity, exocoelom and amniotic cavity following the appearance of the extra-embryonic mesoderm (Rossant and Cross, 2001) (Fig. 1). Subsequent events known as ventral folding morphogenesis lead to the enclosure of the embryo by the yolk sac and amnion, which includes several concurrent rearrangements (turning and axial rotation of the embryo). During this process, the allantois moves so that the umbilical cord is placed in the midline (Gavrilov and Lacy, 2013) (Fig. 2).

Fig. 1 Early development of the mouse embryo from E3.5 to E12.5. (A) The blastocyst consists of the outer and specialized trophectodermal epithelium and the inner cell mass (ICM). Trophectodermal epithelium pumps fluid internally to form the blastocoelic cavity and ICM lies to one side of the cavity. (B) The trophectoderm cells overlying the ICM (polar trophectoderm) continue to proliferate and expand to form extra-embryonic ectoderm and the ectoplacental cone. The trophectoderm cells distal from the ICM continue to form trophoblast giant cells. The endoderm adjacent to epiblast is the visceral endoderm; it will eventually contribute to the yolk sac. (C). The central cavity divides into the ectoplacental cavity, exocoelom and amniotic cavity following the appearance of the extraembryonic mesoderm. Reprinted from Rossant, J., and Cross, J. C. (2001). Placental development: lessons from mouse mutants. *Nature Reviews. Genetics* 2 (7), 538-48, <https://doi.org/10.1038/35080570>, with permission of Springer Nature.

Fig. 2 Ventral folding morphogenesis in the mouse. Upon completion of embryo body turning, the embryo is embedded in the extra-embryonic membranes yolk sac (ys) and amnion (amn). The movement of allantois (al) places the umbilical cord (d) in the midline, at the meeting point of the original anterior and posterior connection sites between the amnion and embryo (* in D). (A) 8–10 somites; (B) 10–12 somites; (C) 12–14 somites; (D) 15–20 somites. Reprinted from Gavrilov, S., and Lacy, E. (2013). Genetic dissection of ventral folding morphogenesis in mouse: Embryonic visceral endoderm-supplied BMP2 positions head and heart. *Current Opinion in Genetics and Development* 23 (4), 461–469, <https://doi.org/10.1016/j.gde.2013.04.001>, with permission from Elsevier.

The third pattern of yolk sac characterizes human and haplorhine primates. The human yolk sac goes through two developmental stages: a primary yolk sac and a secondary yolk sac. A primary yolk sac is formed by extraembryonic endoderm and trophoblast and presents at implantation by proliferation and differentiation of primitive endoderm cells into visceral and parietal endoderm (Fig. 3). The primary yolk sac will break up into small vesicles, and the secondary yolk sac will form from the remnants of the primary yolk sac (Palis and Yoder, 2001) (Fig. 3). The secondary yolk sac, which is not in contact with the trophoblast, serves an important function in embryonic metabolism and maternal-fetal exchange in the first trimester in the human. In the second

Fig. 3 Stages of human yolk sac formation. A. The primary yolk sac (1°YSC) structure in the human implantation site at stage 5c (day 9–12). trimester, expansion of the amnion results in disappearance of the extraembryonic coelom and regression of the yolk sac. Finally, the yolk sac is absent at term (Carter, 2016; Carter and Enders, 2016).

Blood Islands and Hematopoiesis

A role of yolk sac in hematopoietic and vascular induction was demonstrated by classic studies in the chick embryo, and this was supported by that Gata4-deficient embryonic stem cells showing reduced primitive erythropoiesis (Belaoussoff et al., 1998). It has been suggested that the yolk sac blood islands are the first site of hematopoiesis and vascular development in the vertebrate embryo (Baron et al., 2012; Ferkowicz and Yoder, 2005; Golub and Cumano, 2013; Keller et al., 1999; Mikkola and Orkin, 2006; Palis and Yoder, 2001; Tavian and Peault, 2005). Yolk sac blood islands are defined as “a cluster of primitive erythroblasts surrounded by an endothelial covering and nestled between the outer visceral endoderm and inner mesothelial cell layers comprising the yolk sac” (Ferkowicz and Yoder, 2005). Light and electron microscope studies in the mouse have observed the details of the morphological changes that occur during development of the blood islands region (Palis and Yoder, 2001) (Fig. 4). In the mouse, presumptive blood islands arise from mesodermal cell masses or angioblastic cords, which form from proximal mesodermal cells adjacent to visceral yolk sac between E7.0-E7.5 (Palis and Yoder, 2001) (Fig. 4). Blood islands are surrounded by visceral endodermal cells, which face the yolk sac cavity, and the single layer of mesoderm-derived cells, which faces the exocoelomic cavity (Ferkowicz and Yoder, 2005) (Fig. 4). Over the next 24 h, the outer layer of the blood island cell forms a spindle shape, and then these cells differentiate into endothelial cells (Palis and Yoder, 2001) (Fig. 4). The inner cells of blood islands lose their intercellular attachments to differentiate into primitive erythroblasts (Palis and Yoder, 2001) (Fig. 4).

The close spatial and temporal association between blood cells and endothelial cells in the yolk sac blood islands has led to the concept of a common progenitor termed the “hemangioblast” (Baron et al., 2012). Studies from differentiating mouse and human embryonic stem cells support this concept (Choi et al., 1998; Zambidis et al., 2005). Blast colony-forming cells (BL-CFCs) were hypothesized to be the in vitro equivalent of the hemangioblast (Choi et al., 1998). However, the majority of BL-CFCs were not found in the yolk sac but in the posterior primitive streak (Huber et al., 2004). In addition, the BL-CFCs are not strictly bipotential (Tober et al., 2007). Except for primitive and definitive hematopoietic cell types (Tober et al., 2007), they can also differentiate into smooth muscle in vitro (Ema et al., 2003). Therefore, it remains unknown whether an equivalent of the hemangioblast exists in vivo.

There are three distinct waves for hematopoiesis in the mouse (Golub and Cumano, 2013; Jagannathan-Bogdan and Zon, 2013; McGrath and Palis, 2005; Perdiguerro and Geissmann, 2016; Yoder, 2014). In the first wave, the yolk sac blood islands give rise to primitive erythroid progenitors, which are the first hematopoietic cells, from embryonic day 7.0 (E7.0) to E9.0 (Palis, 2014). These cells produce large and nucleated red blood cells that express embryonic hemoglobin molecules in a process known as primitive hematopoiesis. They are well known to be primitive erythroblasts because of their distinguishing features compared to adult red blood cells. Hematopoietic stem cells and lymphoid cells are not produced from the first wave of hematopoiesis. The second wave of hematopoiesis begins at E8.25 (Yoder, 2014). The erythromyeloid progenitors are first produced from vascular hemogenic endothelium as clusters of cells within yolk sac blood island capillaries. They then leave the blood islands, enter the systemic circulation and seed the fetal liver at E10.0. Within fetal liver, they differentiate into red blood cell populations that express adult-type hemoglobin molecules. Hemogenic endothelial cells of the yolk sac and the embryo proper also differentiate into B and T lymphoid progenitors (Boiers et al., 2013; Yoshimoto et al., 2012). The second wave is suggested to be definitive hematopoiesis because

Fig. 4 Yolk sac blood islands formation in the mouse. (A) At E7.5, blood islands form between endoderm cells (E) and mesothelial cells (open arrow). Blood islands develop from undifferentiated mesoderm cells (closed arrow). (B) At E8.5, blood islands contain primitive hematopoietic cells (closed arrow) surrounded by endothelial cells (open arrow) adjacent to visceral endoderm cells (E). Reprinted from Palis, J., and Yoder, M. C. (2001). Yolk-sac hematopoiesis: The first blood cells of mouse and man. *Experimental hematology* 29 (8), 927–936, with permission from Elsevier.

erythromyeloid progenitors produce blood cells with adult-type characteristics and functions. However, this wave does not produce adult-type hematopoietic stem cells (Yoder, 2014). The third wave of hematopoiesis commences at E10.5 with the appearance of hematopoietic stem cells in the aorto-gonad-mesonephros (AGM) region of the embryo and in other arterial vessels of the embryo, yolk sac and placenta at E11.0 (Swiers et al., 2013). In this wave, hematopoietic stem cells produce all the cell types of the multi-lineage hematopoietic hierarchy (Yoder, 2014).

Vasculogenesis

Vasculogenesis is the de novo formation of a network of blood vessels (Garcia and Larina, 2014; Goldie et al., 2008; Jones et al., 2006; Patan, 2004; Patan, 2000). The blood islands located in the proximal extraembryonic yolk sac in the mouse comprise hematopoietic cells surrounded by endothelial cells (Jones et al., 2006) (Fig. 5). These endothelial cells of the blood islands, which expand from a thin band of endothelial and hematopoietic cells, migrate distally into the yolk sac, forming a simple capillary network that covers the yolk sac. This network is known as the primitive capillary plexus (Garcia and Larina, 2014) (Fig. 5). During vasculogenesis, the capillary plexus is initially established by activation of the vascular endothelial growth factor (VEGF) signaling pathway (Goldie et al., 2008; Jeltsch et al., 2013). Vascular endothelial receptor-2 (VEGFR2/flk1) has been identified as a regulator of de novo vasculogenesis and is vital for the development of both the primitive capillary plexus and blood cells during embryogenesis (Goldie et al., 2008; Jeltsch et al., 2013).

Following the establishment of the primitive capillary plexus in the surface of the yolk sac at E8.5, the honeycomb-like vascular network remodels to meet the demands of the expanding yolk sac and the growing embryo as it undergoes rapid morphological changes (Garcia and Larina, 2014). The established vessels expand and increase in diameter and small vessels fuse to form the large major vessels of the embryo and yolk sac. Concurrently, nascent vessels sprout into new, small capillary beds from existing larger vessels. This morphogenetic process is known as vascular remodeling, which occurs between E8.5 and E9.5, and results in a more hierarchical vascular tree (Garcia and Larina, 2014) (Fig. 5). This process is vital for the establishment of the cardiovascular system and support for the growth of the embryo. The viability of the embryo is dependent on the correct vascular remodeling. It has been demonstrated that the Tie family of receptors and ligands are critical molecular mediators for vascular remodeling and initial establishment of the capillary plexus during vasculogenesis (Jeltsch et al., 2013; Jones et al., 2001). Targeted deletion of Tie receptors in mice leads to impairments of vascular development, including yolk sac vascular remodeling (Sato et al., 1995). Four ligands have been identified: angiopoietins 1–4 (Jeltsch et al., 2013; Jones et al., 2001). They regulate vascular remodeling in the mouse embryo by binding to Tie receptors (Jeltsch et al., 2013). Besides Tie family receptors and ligands, members of the transforming growth factor β superfamily (TGF β), including TGFs, bone morphogenetic proteins (BMPs), and activins are molecular regulators of

Fig. 5 Yolk sac vasculogenesis in the mouse. (A) The blood islands located in the proximal extraembryonic yolk sac comprise hematopoietic cells (red) surrounded by endothelial cells (blue). (B) Endothelial cells (blue) of the blood islands expand from a thin band of endothelial and hematopoietic cells (red) and migrate distally into the yolk sac, forming a simple capillary network that covers the yolk sac. The expansion of endothelial cells (blue) from the blood islands occurs earlier than the expansion of hematopoietic cells (red). (C) Following the establishment of primitive capillary plexus in the surface of the yolk sac at E8.5, the honeycomb-like vascular network expands and increases in diameter while small vessels fuse to form the large major vessels of the embryo and yolk sac, resulting in a more hierarchical vascular tree. Reprinted from Jones, E. A., le Noble, F., and Eichmann, A. (2006). What determines blood vessel structure? Genetic prespecification vs. hemodynamics. *Physiology* **21**, 388–395, 10.1152/physiol.00020.2006.

yolk sac vascular remodeling and angiogenesis (Kubis and Levy, 2003). It has been demonstrated that knockout of TGF β family members is lethal at E10.5-E11.5, along with unremodeled yolk sac vasculature, defective endothelial and hematopoietic differentiation, and weak vessels (Garcia and Larina, 2014; Larsson et al., 2001). In addition, it has been demonstrated that Hedgehog and Hippo signalling are required for murine yolk sac vasculogenesis (Byrd et al., 2002; Morin-Kensicki et al., 2006).

Diabetic Vasculopathy

It is well known that maternal diabetes is an independent risk factor for structural birth defects, including congenital heart defects (CHDs) and neural tube defects (NTDs) (Dong et al., 2016; Yang et al., 2015). Data from the National Birth Defects Prevention Study shows that the incidence for newborn NTDs and CHDs are up to 10 times more frequent in women with maternal diabetes compared to women who never had diabetes or who developed diabetes late in pregnancy (Correa et al., 2008). Experimental evidence has demonstrated that maternal diabetes-induced birth defects are associated with the failure of yolk sac vasculogenesis, which is also called vasculopathy (Dong et al., 2016). Morphological scores are assigned to individual vasculature to characterize the adverse effect of hyperglycemia on the yolk sac vasculogenesis (Yang et al., 2008). Using the rating system, it has been demonstrated that hyperglycemia induces significantly lower yolk sac vasculature scores compared to the euglycemic group (Yang et al., 2008). Meanwhile, yolk sac vasculature scores are inversely correlated with embryonic malformations (Yang et al., 2008).

The mouse experiments revealed the abnormal and arrested development of the yolk sac vasculature in the E7.5 embryo, which results in congenital malformations in a wide range of organs and tissues as well as embryonic lethality under maternal diabetic conditions (Nath et al., 2004; Pinter et al., 2001; Pinter et al., 1999; Pinter et al., 1986; Reece et al., 1994; Yang and Reece, 2011). In cultured mouse embryos, exposure to excess glucose leads visceral yolk sac capillaries and vitelline vessels to be sparse, patchy, and not uniformly located (Pinter et al., 1986). In the maternal diabetic mouse model, hyperglycemia causes alteration and disruption of cellular structures of blood vessels in the yolk sac (Pinter et al., 2001; Pinter et al., 1999). Various and profound abnormalities of yolk sac vasculature are observed, including complete lack of vasculogenesis with no apparent arborization or distinction of arteries and veins (Pinter et al., 1997; Pinter et al., 2001; Pinter et al., 1999; Yang et al., 2008) (Fig. 6). The mechanical studies

The yolk sac with a morphological score 0–4. 0 is the worst and 4 is the normal. Scale bar: 1 mm. Reprinted from Yang, P., Zhao, Z., and Reece, E. A. (2008). Blockade of c-Jun N-terminal kinase activation abrogates hyperglycemia-induced yolk sac vasculopathy in vitro. *American Journal of Obstetrics and Gynecology* **198** (3), 321 e1–7, <https://doi.org/10.1016/j.ajog.2007.09.010>, with permission from Elsevier.

show that vascular endothelial cells are the primary target of hyperglycemia (Pinter et al., 1997; Pinter et al., 1999). Hyperglycemia adversely affects the function of endothelial cells, including increased apoptosis, decreased proliferation and differentiation through endothelial cell-dependent molecular pathways: hypoxia-inducible factor-1 (HIF-1); nitric oxide (NO) and nitric oxide synthase (NOS); mitogen-activated protein kinases (MAPKs); and redox sensitive thioredoxin-1 (Dong et al., 2016).

The popular intervention of preventing maternal diabetes-induced birth defects is rigorous glycemic control by antidiabetic drugs and lifestyle alterations (Gabbay-Benziv et al., 2015). However, continuous euglycemic control is difficult to maintain (Reece, 2012). Fortunately, reports have shown the potential for developing therapeutics to treat maternal diabetes-induced birth defects through small molecular targeting of critical sites. Blockage of JNK1/2 activation by JNK1/2-specific inhibitor SP60025 restores hyperglycemia-induced vasculopathy and reduces malformation rates in cultured embryos (Yang et al., 2008). Epigallocatechin-3-gallate (EGCG), a natural antioxidant purified from green tea, also shows a preventive effect on hyperglycemia-induced vasculopathy and congenital malformations (Yang and Li, 2010). In addition, supplementation of thioredoxin, an endogenous antioxidant protein, completely reverses hyperglycemia-induced vasculopathy and congenital malformations by restoring HIF-1 α levels in the yolk sac (Yang and Reece, 2011).

Conclusions and Future Directions

This chapter has summarized what is currently understood about the development and function of yolk sac as well as its association with maternal diabetes-induced birth defects. Although many valuable studies support the claim of yolk sac as the origin of the first blood cells, many unanswered questions remain. Because of ethical issues and difficulty in acquiring human yolk sac samples, most studies on yolk sac development and function are performed by using the mouse model. However, it is unclear whether mechanical studies on mouse yolk sac are relevant to human yolk sac because of differences between human and mouse in yolk sac development and shape. The mechanism underlying the yolk sac's extreme sensitivity to hyperglycemia exposure, which leads to diabetic vasculopathy, is still elusive. More studies are needed to investigate therapeutic interventions that target yolk sac to prevent birth defects induced by maternal diabetes.

Allantois

Fuller W Bazer and Gregory A Johnson, Texas A&M University, College Station, TX, United States

© 2018 Elsevier Inc. All rights reserved.

Glossary

Allantoic membrane The allantoic membrane of the placenta forms as an evagination of the hindgut to form a sac filled with allantoic fluid composed of water, urine, nutrients (e.g., amino acids, glucose, vitamins, and minerals), growth factors, hormones, and enzymes that support growth and development of the conceptus.

Conceptus refers to the embryo/fetus and its associated placental membranes.

Placenta refers to the amnion, allantois, and chorion that collectively form the unit for the exchange of nutrients and gases between the maternal and fetal–placental vascular systems.

Umbilicus is the stalk connecting the fetus to the placenta. It contains major blood vessels and the urachus that connects the fetal bladder and allantoic sac.

Urachus is a duct that transports the contents of the bladder into the allantoic sac. This fluid from the bladder includes water, urea, proteins, nutrients, and other molecules that are cleared by the fetal kidney into the bladder.

Introduction

The allantoic membrane forms as an evagination of the hindgut (endoderm) as a diverticulum covered by mesoderm (splanchnopleure) (see Fig. 1). The allantoic membrane dilates and extends outside the embryo/fetus except for attachment by the umbilical stalk that contains the urachus for communication between the fetal bladder and allantoic sac. The allantoic membrane acquires an extensive blood supply from caudal branches of the aorta that break up into an extensive vascular net. The allantois and chorion fuse early in gestation so that the vascular system of the allantoic membrane supplies the entire chorioallantoic placenta.

The placental membranes of most subprimate mammals are of the chorioallantoic type that includes the yolk sac, amnion, allantois, and chorion (Perry, 1981). The yolk sac develops from about day 14, is maximum in size by about day 18, and becomes

Fig. 1 Diagram of the fetal membranes depicting outgrowth of the allantoic membrane from the hindgut. The drawing indicates that the vasculature of the placenta resides in the allantois. Water, sugars, amino acids, and proteins are cleared from the fetal–placental circulation by the kidney into the bladder, and the contents of the bladder enter the allantoic sac via the urachus. This allows most components of the so-called urine, such as glucose, fructose, and amino acids, to be recycled. That is, those nutrients and many of the proteins can reenter the fetal–placental circulation to nourish the fetal–placental tissues. Thus, the allantoic sac is a major reservoir of nutrients rather than a reservoir for wastes as claimed in many textbooks.

vestigial after day 20 of pregnancy. Soon after the hindgut of the embryo is established, a diverticulum known as the allantois develops from the splanchnopleure. Thus, the allantoic membrane forms as a diverticulum of the hindgut (endoderm) covered by mesoderm (splanchnopleure). The allantoic membrane dilates and extends outside the embryo/fetus except for attachment by the umbilical stalk that contains the urachus for communication between the allantoic sac and fetal bladder (Bazer, 1989).

The porcine allantoic epithelium is a simple columnar epithelium with angular cells and a fine foamy cytoplasm containing large amounts of glycogen and small lipid granules (Naaktgeboren et al., 1975). The glycogen disappears in late gestation. The allantoic epithelium of pigs is dimorphic granular cells and mitochondria-rich cells with the ratio of granular cells predominating at a ratio of about 40:1. The granular cells may release proteoglycans, which provide a mucous covering of the epithelium. These cells are asymmetrical due to a thickening of the apical plasmalemma; however, the significance of the asymmetry is not known. Similarly, the function of the mitochondria-rich cells is unknown, but they are rich in cAMP and may also play a role in the regulation of water and solute flux. The allantoic sac was originally considered a reservoir for fetal urine, and the mesonephric glomeruli were thought to be the source of allantoic fluid (Bazer and First, 1983; Buhi et al., 1983). However, it is now well established that the urinary system does not make water, but only redistributes available water that must be derived from the maternal system. Water may enter the allantoic sac from the embryo/fetus via the kidney, bladder, and urachus, or water may be transported directly across the chorioallantois into the allantoic sac (Gresham et al., 1972). Ligation of the urachus in sheep fetuses between days 85 and 127 of gestation results in the disappearance of allantoic fluid, which indicates that water and other molecules enter the allantoic sac via the urinary system of the fetus.

Functions of the Allantoic Membrane

The allantoic membrane acquires an extensive blood supply from caudal branches of the aorta that break up into an extensive vascular network. The allantois and chorion fuse early in gestation so that the vascular system of the allantoic membrane supplies the entire chorioallantoic placenta. In the pig, the allantoic membrane does not expand to fill the entire chorionic vesicle; therefore, the extreme ends of the chorion become necrotic due to the lack of a vascular supply from the allantoic membrane (see Fig. 1). The allantoic membrane forms a sac and accumulates allantoic fluid, which is of both maternal and fetal (urine) origin. The components of allantoic fluid include water, glucose, fructose, amino acids, electrolytes, proteins, hormones, and growth factors, which accumulate for immediate recycling into the fetal circulation (e.g., fetal transferrin), for use as metabolic substrates (e.g., glucose and fructose), or for synthesis of peptides and proteins (amino acids) by the conceptus. The allantoic membrane is derived from splanchnopleure (mesoderm and endoderm) and can transport nutrients into the fetal circulation.

The transports of water, electrolytes, and nutrients into the allantoic sac are influenced by the presence of aquaporins, sex steroids (estrogen and progesterone), and extracellular matrix proteins such as secreted phosphoprotein 1 (also known as osteopontin) (see Bazer, 1989). Transport of water into the allantois expands the allantoic sac, which brings the allantoic membrane into apposition with the chorion and then the chorioallantoic placenta into intimate contact with the maternal uterine endometrium. Temporal changes in allantoic fluid volume are accompanied by essentially identical changes in the total amounts of glucose and fructose in the allantoic sac of sheep and swine. Total protein in allantoic fluid of sheep increases throughout gestation, which is consistent with evidence that secretory activity of uterine endometrial glands increases throughout gestation. Secretions of the uterine glands are transported into the fetal-placental circulation via the areolae and enter the allantoic sac via the urachus if not metabolized by the fetus. Total protein in allantoic fluid of pigs increases from day 20 to day 75 of gestation and then decreases to term (day 114 of gestation). This is true for proteins in general and for progesterone-induced proteins such as uteroferrin (also known as acid phosphatase type 5 and tartrate-resistant acid phosphatase). Uteroferrin is secreted by the uterine glandular epithelium in response to progesterone, transported into the fetal circulation, and cleared into the allantoic sac if not taken up by reticuloendothelial cells of the fetal liver. The role of uteroferrin is to transport iron from the uterine endometrial glands to the fetal-placental unit, and there is evidence that it stimulates hematopoiesis (Bazer et al., 1991; Ying et al., 2014).

Humans Lack an Allantoic Membrane

In humans, the allantoic membrane does not form a sac filled with allantoic fluid (Perry, 1981). Rather, the allantoic membrane is represented by an endodermal outgrowth from the hindgut that fuses with the chorion and develops blood vessels, thus participating in the formation of the umbilical cord.

The Amnion and Amniotic Fluid

Aisling Murphy and Brian Koos, University of California, Los Angeles, Los Angeles, CA, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Throughout gestation, the amniotic fluid (AF) not only protects the fetus from trauma, but also permits normal fetal growth and movement, and prevents compression of the umbilical cord. Its bacteriostatic properties defend against infection and analysis of AF enables prenatal genetic diagnosis. AF also provides an acoustic interface that facilitates fetal ultrasound imaging. Disorders of amniotic fluid volume are among the most common obstetric complications and arise from a diverse number of underlying pathological processes. This chapter reviews amnion embryology, AF volume regulation and clinical disorders of amniotic fluid volume.

Embryology

Humans belong to amniotes, a large vertebrate subgroup with a fluid-containing membrane (amnion) encapsulating the embryo. The development of an amnion enabled our remote tetrapod ancestors to lay their eggs on land rather than in water, and therefore ranks as among the most important evolutionary developments (Hickman et al., 2013).

The human blastocyst contains an outer layer of trophoctodermal cells and an inner cell mass. Before implantation, the inner cell mass differentiates into two layers. Epiblast, the outer upper layer, is the morphologic precursor to the amnion, which ultimately encompasses the entire embryo and surrounding fluid. The hypoblast underlying the epiblast forms the endodermal lining of the yolk sac. Developing ventral to the epiblast, the extra-embryonic mesoderm becomes the inner layer of the chorionic membrane (Fig. 1; Carlson, 2014). The trophoctodermal cells of the cytotrophoblast and syncytiotrophoblast form the outer layer.

The enlarging amnion completely surrounds the embryo upon merging with the body stalk, a precursor of the umbilical cord. The amnion forms the epithelial layer of the umbilical cord. Surrounding the amnion is the chorionic cavity or extra-embryonic coelom, which is formed within the extra-embryonic mesoderm (Fig. 2; Carlson, 2014). In early gestation, the coelomic cavity is filled with fluid, but at the end of the first trimester (12–14 weeks' gestation) the enlarging amnion fuses with the chorion, obliterating the coelomic cavity.

Amniotic Fluid Circulation in Early Gestation

The coelomic cavity, (secondary) yolk sac, and amniotic cavity are present in the first-trimester. Coelomic fluid (CF) has a similar composition to maternal plasma, suggesting that CF is an ultrafiltrate of maternal plasma (Jauniaux and Gulbis, 2000).

The very early origin of amniotic fluid is CF rather than the fetus, since AF is present in anembryonic gestations (Seeds, 1980). Later on in the first trimester, the compositions of CF and AF differ significantly (Campbell et al., 1992, 1993; Jauniaux and Gulbis, 2000), and at this time transudation of fluid and nutrients across the non-keratinized epithelium appears to be a major source of AF (Jauniaux et al., 1994). The magnitude of contribution from the maternal circulation across the chorion and amnion (transmembranous pathway) in the first trimester is unknown.

Amniotic Fluid Circulation in Late gestation

Fetal Urine

Fetal urine contributes to AF volume when the kidneys begin to function by the end of the first trimester. Fetal urine becomes the major source of AF once fetal skin is keratinized in the second trimester. The volume of urine production has been estimated using ultrasound assessment of fetal bladder volume. These data suggest that fetal urine output increases from 110 mL/kg fetal weight/day at 25 weeks up to approximately 200 mL/kg fetal weight/day at term (Rabinowitz et al., 1989; Fägerquist et al., 2001). Fetal urine production decreases after 40 weeks' gestation (Abramovich et al., 1979; Wladimiroff and Campbell, 1974).

Fetal Lung Fluid

Another major source of AF is the secretion of pulmonary fluids. Based on animal studies, fetal lungs excreted about 60–100 mL/kg fetal weight/day (Gilbert and Brace, 1993). About half of the volume flows into the amniotic cavity, while the other portion is swallowed.

Fetal lung fluid differs from urine in having a higher chloride content, and lower concentration of protein and bicarbonate. Pulmonary phospholipids are present, particularly in late gestation. These phospholipids are critical for postnatal lung function, and levels in AF can provide a risk assessment for neonatal respiratory distress syndrome.

Fig. 1 (A) Late blastocyst. (B) Beginning of implantation at 6 days. (C) Implanted blastocyst at 7.5 days. (D) Implanted blastocyst at 8 days. (E) Embryo at 9 day. (F) Late second week. Reproduced from Carlson, B. (2014). *Formation of germ layers and early derivatives. Human embryology and developmental biology* (5th edn.) Elsevier (Chapter 5).

Lung fluid secretion is essential for normal lung development. Cortisol and catecholamines lower lung fluid production. Neonates who have undergone the forces of vaginal delivery have higher levels of these hormones than those delivered by cesarean. The higher hormone concentrations enhance clearance of lung fluid as the fetus transitions to postnatal life and likely account for the lower rates of transient tachypnea in vaginally delivered newborns.

Very little amniotic fluid (< 2 mL) is normally exchanged per single breathing movement. But the train of breaths in a breathing episode increases lung volume, and this expansion contributes to lung growth (Harding and Hooper, 1996). Hypoxia normally inhibits breathing movements, but severe hypoxia/asphyxia can elicit intermittent, strong gasping efforts. Large transthoracic pressure gradients produced by isolated gasps can result in a net inflow of amniotic fluid. This phenomenon is supported by autopsies of stillborn infants revealing meconium in the pulmonary tissue (Brown and Gleicher, 1981) and by the finding of meconium aspiration syndrome in neonates without postnatal aspiration (Byrne and Gau, 1987; Sarno Jr et al., 1990).

Intramembranous Pathway

The intramembranous pathway involves absorption of AF across the vasculature of the chorionic plate into the fetal circulation. The amount of fluid passing through this pathway is highly variable, ranging from 200 to 500 mL per day (Wintour and Shandley, 1993) (Fig. 3).

Transmembranous Pathway

The transmembranous pathway involves fluid passage through fetal membranes to the maternal blood in capillaries within the uterine wall. This pathway has a minimal effect of AF volume with only about 10 mL/day transferred at term (Gilbert and Brace, 1993; Seeds, 1980).

Fig. 2 Origins of the major extraembryonic tissues. Reproduced from Carlson, B. (2014). Formation of germ layers and early derivatives. *Human embryology and developmental biology* (5th edn.) (Chapter 5).

Fetal Swallowing

Fetal swallowing is the predominant AF outflow, about 200–250 mL/kg fetal weight/day (Abramovich et al., 1979). Although swallowing activity can be observed in late first trimester, these movements become well-coordinated with behavioral states only in later gestation (Grassi et al., 2005). Dipsogenic (thirst) and orexigenic (appetite) pathways stimulate swallowing activity in near-term fetal sheep (Xu et al., 2001; El-Haddad et al., 2004). Fetal swallowing is also augmented by increased volume of AF, decreased

Fig. 3 Amniotic fluid pathways. Reproduced from Underwood, M. A., Gilbert, W. M. and Sherman, M. P. (2005). Amniotic fluid: Not just fetal urine anymore. *Journal of Perinatology* 25(5), 341–348.

AF osmolarity and elevated fetal plasma osmolarity (Moore, 2010). On the other hand, fetal swallowing diminishes in response to oligohydramnios, hypotension, and hypoxia (Brace et al., 1994; Sherman et al., 1991).

Fetal CNS lesions (e.g., anencephaly) and some neuromuscular disorders can elicit polyhydramnios by inhibiting fetal swallowing. Likewise, conditions interrupting passage of AF through the gastrointestinal tract (e.g., esophageal or duodenal atresia) can also cause polyhydramnios. In obstruction cases without polyhydramnios, AF volume is likely normalized via the intramembranous pathway.

Composition of Amniotic Fluid

Early Gestation (First Trimester)

AF is isotonic with fetal plasma with very low protein concentrations except for α -fetoprotein. AF is a milieu of low oxygen tension. High levels of polyols are present, suggesting activity of the polyol pathway, which is involved in generating NAD⁺ from NADH. Given the low oxygen tensions of embryonic tissues, increased NADH production allows glycolysis to continue, while limiting lactate generation and fall in pH (Jauniaux et al., 2005). This pathway is also involved in the production of precursors for nucleic acids, important in rapidly dividing tissues.

Later Gestation (Second and Third Trimesters)

With keratinization of fetal skin, AF approximates urine in composition, containing carbohydrates, proteins, amino acids, and lipids, as well as the electrolytes, enzymes, and hormones (Underwood et al., 2005). Amino acids levels drop across gestation and are lower than serum levels, with the exception of taurine (Reid et al., 1971; Kerr and Kennan, 1969; Cockburn et al., 1970). In the ovine fetus, swallowed AF amino acids appear important in the development of the intestinal mucosa (Kwon et al., 2003). Swallowed AF lipid and carbohydrates unlikely contribute significantly to fetal nutrition, and nutritional supplementation via AF does not improve weight-gain in experimental fetal growth restriction (Buchmiller et al., 1994).

AF contains multiple growth factors including epidermal growth factor, transforming growth factor alpha, transforming growth factor beta-1, insulin-like growth factor I, erythropoietin, and granulocyte colony stimulating factor. These substances appear to have significant trophic effects in the intestinal mucosa (Underwood et al., 2005). Antimicrobial substances are also present in AF, such as α -defensins [HNP1–3] and lactoferrin (Underwood et al., 2005).

Amniotic Fluid Volume

Based on dye dilution studies, AF volume normally rises progressively from early pregnancy to about 32–34 weeks and thereafter declines until delivery (Brace and Wolf, 1989). The normal range of AF across gestation is quite broad. The decline in AF volume may involve relative changes in swallowed fluid relative urine production as well as alterations in fluid transfer across the intramembranous pathway (Fig. 4).

Regulation of Amniotic Fluid Volume

AF volume changes little from day to day, despite the daily fluid turnover. Thus, AF volume is regulated. Fetal sheep studies indicate that the intramembranous pathway is the primary controller of AF volume (Brace and Cheung, 2014). Putative components of this

Fig. 4 Amniotic fluid volumes as a function of gestational age. Shaded area covers 95% confidence interval. Reproduced from Brace, R. A., Wolf, E. J. (1989). Normal amniotic fluid volume changes throughout pregnancy. *American Journal of Obstetrics and Gynecology* **161**, 382.

regulatory pathway include chorioamnion vascular endothelial growth factor (Matsumoto et al., 2001; Feng et al., 1999; Cheung et al., 2010; Shandley et al., 1997), transmembrane water channels (aquaporins) (Brace and Wolf, 1989; Mann et al., 2006; Beall et al., 2007) absorption inhibitors in fetal urine, intra-amniotic prostaglandin E₂ via its stimulation of vascular endothelial growth factor production in the fetal membranes and membrane stretch via a negative feedback effect (Brace and Cheung, 2014).

Assessment of Amniotic Fluid Volume

Estimation of AF volume involves ultrasound measurement of the maximum vertical pocket or the four quadrant sum of the deepest vertical pockets, the amniotic fluid index (AFI). Excessive AF volume (polyhydramnios) is generally identified with a single pocket > 8 cm or AFI > 25 cm with low volumes (oligohydramnios) having a single pocket < 2 cm or AFI < 5 cm. These extremes of AF volume have important clinical implications.

Polyhydramnios. Complicating about 1% of pregnancies, polyhydramnios is associated with variety of conditions including maternal diabetes mellitus, malformations which may inhibit fluid passage through the gastrointestinal tract, neuromuscular impairments which may inhibit fetal swallowing, and fetal anemia (Table 1). About 40% of cases are unexplained. Polyhydramnios increases the risk of a number of complications, including preterm labor, cesarean delivery, stillbirth, cord prolapse, and postpartum hemorrhage (Biggio Jr et al., 1999; Pilliod et al., 2015). The enlarged uterus can also cause shortness of breath in the mother.

Oligohydramnios. The progressive fall in AF after about 32 weeks increases the prevalence of oligohydramnios, particularly after 41 weeks' gestation. The normal decline in AF volume is likely due to changes in fluid transfer via the intramembranous pathway. Oligohydramnios can also accompany premature (before onset of contractions) rupture of the membranes, fetal growth restriction, renal disorders, and chronic disruptions in placental function. Early onset, severe oligohydramnios greatly increases risk of pulmonary dysplasia and compression abnormalities of the fetus. Preterm (< 37 weeks) premature rupture of the membranes only complicates 1%–2% of pregnancies but is a major cause of preterm birth and its adverse sequelae. Even at term, oligohydramnios increases fetal morbidity and mortality (Shipp et al., 1996; Sarno Jr et al., 1990; Chauhan et al., 1999) (Table 2).

Summary

The amnion arises from the epiblast cells of the blastocyst and grows to surround the developing embryo, creating a fluid-filled cavity. Thus, throughout prenatal life, humans are surrounded by AF. This fluid serves many functions critical for prenatal development. In very early gestation AF appears to arise from the nearby coelomic cavity. As the fetus grows, the transudation of fluid across the fetal skin becomes an important source of fluid. In second trimester, after keratinization of the fetal skin, fetal urine becomes the

Table 1 Causes of polyhydramnios

Idiopathic
Fetal macrosomia
Maternal diabetes
Gastrointestinal anomalies, e.g., cleft palate, esophageal atresia, duodenal atresia, annular pancreas, jejunal atresia, volvulus, gastroschisis
CNS lesions/musculoskeletal disorders, e.g., anencephaly, hydranecephaly, microcephaly, encephalocele, myoclonic dystrophy, Pena-Shokeir syndrome, fetal akinesia syndrome
Obstructive chest lesions, e.g., congenital diaphragmatic hernia, CPAM
Hydrops/fetal high output cardiac failure—isoimmunization, congenital cardiac lesions, fetal arrhythmias, TORCH infections, Alpha thalassemia, fetal anemia, sacrococcygeal teratoma, chorioangioma
Twin to twin transfusion syndrome
Aneuploidy—trisomy 18, trisomy 21
Skeletal dysplasias—osteogenesis imperfecta, thanatophoric dysplasia
Renal disorders—unilateral uteropelvic junction obstruction, Bartter syndrome

Table 2 Causes of oligohydramnios

Rupture of membranes
Placental insufficiency/fetal growth restriction/placental abruption
Postterm pregnancy
Fetal urinary tract anomalies, e.g., renal agenesis, multicystic dysplastic kidneys, polycystic kidneys, fetal bladder outflow tract obstruction, bilateral ureteropelvic junction obstruction
Maternal medications, e.g., prostaglandin synthetase inhibitors, angiotensin converting enzyme inhibitors
Chromosomal anomalies
Other causes, e.g., donor twin in twin to twin transfusion syndrome, fetal demise

primary source of AF, with a lesser contribution from lung fluid. Fluid is removed from the cavity by fetal swallowing and via absorption back into the fetal circulation, known as the intramembranous pathway.

AF volume normally rises to a peak in the early third trimester, and then subsequently declines. Estimation of AF volume can be made by use of prenatal ultrasound and disorders of AF volume are common obstetric complications.

Glossary

Adiposity rebound The point during childhood at which body fatness declines to its minimum point, before rising again into adulthood. The age of adiposity rebound is typically 3–7 years of age.

Body mass index (BMI) A classification measure used for defining an individual as underweight, normal weight, overweight or obese; calculated as body weight (kg)/height (m)².

Epigenetics The study of environmental influences on a phenotypic outcome through modulation of gene expression by way of post-transcriptional regulation of mRNA, post-translational modifications to DNA associated proteins, and/or chemical modification of DNA without changing the underlying genetic code.

Hypoxia Deficiency in the amount of oxygen available to a tissue, usually induced either by lack of oxygen reaching tissues, or by increased metabolic demand beyond what can be sustained by oxidative metabolism.

Methyl donor Molecules which partake in enzymatic transfer of a methyl (–CH₃) group to another recipient molecule (i.e., DNA).

Non-communicable disease (NCD) A chronic medical condition that is not caused by an infectious agent and is thereby not transmissible from one individual to another.

Oxidative stress A state of imbalance in which cells produce free radicals (including reactive oxygen species) at rates faster than they can be metabolized/detoxified. This results in an accumulation of reactive intermediates, imbalance in cellular redox state, and damage to cellular components, including nucleic acids and organelles.

Ponderal index (PI) A measure of whole body adiposity or thinness; calculated as body weight (kg)/height (m)³.

Socioeconomic status (SES) A sociological measure of a person's or family's social and economic position relative to others. The main factors considered when determining SES are income, level of education, and occupation.

The metabolic syndrome A cluster of symptoms indicative of risk for the development of serious, life-threatening health complications. Symptoms include central obesity, hypertriglyceridemia, reduced high-density lipoprotein levels, hypertension, and elevated fasting blood glucose levels. Possessing three or more of these symptoms qualifies a diagnosis of this syndrome.

Nutrition, Pregnancy, and Disease—A Developmental Origins Hypothesis

Adequate nutrition during pregnancy has long been appreciated for its importance in promoting fetal growth and development up to the time of birth. It is only within the last three decades, however, that the impacts of periconceptional nutrition on embryonic and fetal development have emerged as key determinants of later life health and chronic disease risk. Some of the first evidence to demonstrate the importance of the intrauterine environment in mediating fetal growth and postnatal outcomes came from embryo transfer and artificial insemination experiments, in both humans and other mammals. These studies showed that fetal size at birth was more closely related to the size of the mother carrying the fetus, rather than paternal size, or size of the embryo donor (Brooks et al., 1995; Walton and Hammond, 1938). This evidence strongly supported the prevailing concept of maternal constraint, where maternal size, available nutrient stores, and energy demand, as opposed to genetics, strongly influence fetal growth trajectory in utero and impacted on postnatal phenotype.

More recently, an extended role for nutrition during pregnancy has been established. It is now known that maternal nutrition before and during pregnancy and its impact on fetal development determine not only size at birth, but also long-term growth trajectory and health potential across the life course, a theory known as the Developmental Origins of Health and Disease (DOHaD). Pioneering work in this field came from epidemiologist and physician, Dr. David Barker, where in a nationwide study of mortality rates from cardiovascular disease (CVD) in England and Wales, Barker saw that the areas with the highest incidence of neonatal and infant mortality in the early 20th century were the same areas with the highest incidence of death from CVD > 60 years later (Barker and Osmond, 1986). This finding contrasted with the notion that heart disease was a disease of affluence and nutritional excess, and not due to low socioeconomic status (SES). The findings from this study led Dr. Barker to hypothesize that predispositions to *non-communicable disease* (NCDs) or chronic diseases such as CVD, are established based on the early life environment, including those conditions found in utero. In a subsequent study, Barker and his colleague Charles Nicholas Hales demonstrated that the risk for developing Type 2 diabetes was inversely related to a child's birth weight, a surrogate measure for intrauterine growth and nutrition (Hales et al., 1991, Fig. 1A). Follow up studies in European, North American, and Asian populations have confirmed these same associations (Hales and Barker, 2001). One of the largest, The American Nurses Study, examined the risk of later life CVD

Fig. 1 Low birth weight is associated with increased risk of later life cardiometabolic disease in two separate birth cohorts. (A) In a study of >800 men over the age of 64 Barker et al. discovered a significant, inverse association of birthweight with risk of developing diabetes later in life. Of note, risk increases with on the far end of the spectrum. (B) The American Nurses study, consisting of a cohort of >70,000 women, demonstrated a similar trend to that observed in Hertfordshire, between birth weight and relative risk of developing coronary heart disease. (A) Data adapted from Hales, C.N., Barker, D.J., Clark, P.M., Cox, L.J., Fall, C., Osmond, C. and Winter, P.D. (1991). Fetal and infant growth and impaired glucose tolerance at age 64. *BMJ* **303**, 1019–1022. (B) Data adapted from Rich-Edwards, J.W., Stampfer, M.J., Manson, J.E., Rosner, B., Hankinson, S.E., Colditz, G.A., Willett, W.C., Hennekens, C.H., (1997). Birth weight and risk of cardiovascular disease in a cohort of women followed up since. *BMJ* **315**, 396–400.

in over 70,000 female participants for whom birth records were available. Here, the inverse relationship that was reported in Hertfordshire was similarly observed (Fig. 1B) and was not weakened by controlling for SES or adult lifestyle (Rich-Edwards et al., 1997).

Since the initial Barker data, numerous studies investigating the DOHaD hypothesis have reported associations between birth weight and neonatal and infant body mass index (BMI), ponderal index (PI), and placental size and morphology, with physiological and disease outcomes including glucose intolerance, insulin resistance, Type 2 diabetes, hypertension, obesity, precocious puberty, allergy, and asthma. As a part of these observations, when intrauterine growth restriction (IUGR, also known as fetal growth restriction (FGR)) occurs, the development of certain organs, primarily the brain, is spared at the expense of other tissues including muscle, liver, and pancreas. It has been proposed that the fetus adapts in utero by adjusting set points of *metabolic homeostasis* to respond to the perceived nutrient availability in the postnatal environment. In doing so, the fetus alters its metabolism to make the best of use of the limited nutrient supply, a theory termed by Barker and his colleague Charles Nicholas Hales as the *Thrifty Phenotype Hypothesis* (Hales and Barker, 2001).

As a part of adopting a “thrifty phenotype”, it has been suggested that the fetus makes predictive adaptive responses (PARs); processes that lead to changes in the phenotype of the developing individual not for immediate survival, but in expectation of future advantage in the postnatal environment. In the case of nutrient restriction, some have hypothesized that the fetus sacrifices growth of certain organs (by limiting cellular division) thereby reducing overall metabolic demand. For example, a decrease in muscle fiber number, with concomitant decreases to muscle insulin sensitivity, will spare glucose uptake. Similarly, a reduction in fetal pancreatic insulin-producing β -cells would spare stimulation of glucose uptake in insulin sensitive tissues. These functional adaptations make glucose, the primary fetal energy substrate, more available to tissues such as the brain—an organ that is less evolutionarily dispensable (Hales and Barker, 2001). In a sense, the fetus becomes metabolically programmed to respond appropriately to the perceived nutrient poor environment outside of the womb. While these adaptations may confer an advantage if the accessibility of nutrients in the intrauterine environment is reflective of the actual postnatal environment, if a mismatch between pre- and postnatal occurs regarding perceived and actual nutrient availability, these responses (i.e., decreased insulin sensitivity or production) may be maladaptive and lead to progressive, chronic metabolic disease (i.e., Type 2 diabetes).

Several epidemiological and experimental studies have shown that pregnancy outcomes and associated programming effects apply to all facets of nutritional balance. Below we outline the evidence of how nutritional imbalance during pregnancy impacts fetal and placental growth, pregnancy outcomes, and later life adult disease risk.

Maternal Nutrient Restriction and Later Life Disease Risk

Much of our understanding of how nutrition, especially undernutrition, during pregnancy influences offspring health throughout the life course comes from epidemiological studies utilizing large birth cohorts exposed to nutritional challenges during pregnancy due to war, natural disaster, or political unrest. By comparing data collected from these women and their offspring, to those residing in the same geographic area before or after the period of disaster, epidemiologists have been able to use these “natural experiments” to test the effects of maternal malnutrition on pregnancy outcomes and later life disease risk in humans.

Epidemiological Evidence

The Dutch Hunger Winter of 1944–1945 has provided a wealth of information in this regard. During the second World War, German occupation of The Netherlands led to a complete blockade of food and fuel resulting in a five-month period from December 1944 to April 1945 in which the average individual caloric intake varied from 400 to 800 kcal per day. Although this restriction was rapidly lifted in May 1945 with liberation by the Allied forces, this short but severe famine period allowed the examination of pregnant women based on their window of exposure to caloric restriction. Several important observations were made from studies of the Dutch famine cohort, the most important being that fetal growth and the long-term effects of maternal nutrient restriction were dependent on the timing of exposure. Offspring born to mothers exposed exclusively during early gestation were born with a normal birth weight, but as adults, had an atherogenic lipid profile, obesity, early onset coronary heart disease, increased reactivity to stress, and higher rates of breast cancer. In contrast, offspring exposed later in pregnancy were born low birth weight (LBW) with fewer adult physiological complications. Critically, all exposed adult offspring demonstrated impaired glucose tolerance and insulin resistance, independent of timing of exposure, suggesting metabolic regulation is particularly vulnerable to changes in prenatal nutrient intake ([Roseboom et al., 2006](#)). These findings were some of the first to offer insight into the later life consequences of nutrient deprivation for pregnancy outcomes and later life metabolic disease.

The Dutch Hunger Winter was not the only famine cohort to be studied. The Siege of Leningrad (now St. Petersburg) by German forces in the second World War lasted from September 1941 to January 1944 and prevented food rations from entering the city for 872 days. It is estimated that 30%–40% of the population died of starvation, and during the height of the famine the average bread ration contained 300 calories with negligible protein content. Between 1941 and 1942 the total number of live births dropped from 3056 to 468, and neonatal mortality nearly doubled. Many newborns during this time were born well below the normal weight range, and had no sustained weight gain before being discharged from the hospital after birth, with some even losing weight further ([Antonov, 1947](#)). No association between maternal nutrient deprivation during pregnancy and later life metabolic disease in offspring has been demonstrated in this cohort ([Rotar et al., 2015](#); [Stanner et al., 1997](#)). While some have pointed to this as evidence against the DOHaD hypothesis, others see it as supportive evidence that timing of nutritional challenge and mismatch between pre- and postnatal environments are key drivers behind developing later life metabolic disease. Where the Dutch Hunger Winter was very short and saw rapid restoration of normal nutrient availability at the end of the blockade, the Leningrad Siege in contrast lasted almost 3 years, and saw a period of continued malnutrition for years following the end of The Siege. Offspring born during The Siege would have had a high level of congruency between nutritional deprivation in utero and in early childhood, whereas offspring of the Dutch cohort would have had a high level of mismatch between the fetal and infant life. It is possible that the level of compatibility between the early life and adult environment would determine whether the adaptations made during fetal life would be suitable for life outside of the womb, and thus dictate whether metabolic disease ensued.

In support of this theory of mismatch, in the Chinese Great Leap Forward Famine cohort of 1959–1961—a famine of similar length to Leningrad—programming effects were dependent on whether individuals lived in rural or urban areas after the end of the famine. Those offspring who were exposed to famine and lived in urban areas, where food was more accessible in greater quantities, were more prone to developing hypertension compared to their counterparts living in rural areas, where food availability was similar to what was predicted in utero ([Wu et al., 2017](#)). The disparity between these groups regarding exposure and postnatal nutrient availability highlights the interaction between fetal adaptations and the postnatal environment, and how a mismatch can result in postnatal disease risk ([Duque-Guimarães and Ozanne, 2013](#)). A second important observation to come from this cohort was that some outcomes were dependent on offspring sex. Males exposed to famine during pregnancy were more likely than females to develop non-alcoholic fatty liver disease (NAFLD) ([Chen et al., 2016](#)). In contrast, more females were born to mothers exposed in mid-to-late pregnancy ([Song, 2014](#)). These data might suggest that male fetuses were more sensitive to nutrient deprivation in the womb, and less equipped to adapt to poor nutrition.

Investigations of other cohorts support these observations. In a study of over 13,000 men and women born in Helsinki, Finland from 1934 to 1944 it was demonstrated that babies with a low ponderal index (PI, a measure of thinness at birth) and low BMI at 2 years of age, showed an early *adiposity rebound*, and that these children had a high BMI at 11 years of age ([Barker et al., 2009](#)). It is suggested that a low PI might indicate a forfeiture of muscle mass in favor of other organs (such as the brain), and that accelerated postnatal “catch-up” growth early in infant life is associated with a decreased ratio of lean muscle mass to fat mass. It is this combination of factors that is thought to contribute to the development of the *metabolic syndrome* in adulthood ([Eriksson et al., 1999, 2003](#)).

Adequate availability of macronutrients is not the only factor important during pregnancy. Epidemiological studies have found that the *balance* between calories derived from specific macronutrients during gestation can be equally as important. In a cohort of

253 men and woman born in the Aberdeen Maternity Hospital, it was demonstrated that an imbalance between calories consumed from animal protein and those from carbohydrate (i.e., high-carb, low-protein, or low-carb, high-protein diet) tended to decrease placental size and was associated with hypertension in later life (Campbell et al., 1996). As the fetus is entirely dependent upon the placenta for transport of nutrients, altered placental growth and function because of poor maternal nutrition is as equally important as, and likely responsible for, changes in fetal growth. Indeed, several studies have shown relationships between maternal fat mass, and diet with placental morphology and function (Alwaseel et al., 2010; Godfrey and Barker, 1995; Huppertz et al., 2006; Roseboom et al., 2011; Winder et al., 2011). Taken together, these studies indicate that poor maternal nutrition impairs the number of cells present in, and the function of metabolic organs, which have long term consequences for the health and longevity of the offspring in adult life.

While famine cohorts offer insight into associations between poor nutrition and outcome, they do little to uncover the cellular and biochemical mechanism(s) controlling fetal adaptation to changes in nutrition. Proxy measures such as birth weight, BMI and ponderal index are poor informants of intrauterine growth patterns and organ development. Many of the observed effects are prone to survivor bias, where only those with a strong enough constitution to survive the effects of gestational famine make up the study population, which could lead to misrepresentation of the severity of effects. This is where animal models have been invaluable in uncovering the mechanisms underlying nutrient deprivation.

Experimental Evidence

Animal models of nutrient restriction prior to and during pregnancy, and into lactation, have allowed researchers to isolate specific biological metabolic programming mechanisms. The most commonly used organisms in these studies have been rodents, guinea pigs, and sheep, although studies in non-human primates are increasing. While there are many similarities among mammalian pregnancies, notable differences exist regarding the number of offspring in a single pregnancy, the metabolic adaptations made during pregnancy, and the type of placentation. As such, these factors must be considered when selecting an animal model and interpreting the applicability of data to human populations.

Caloric restriction models

Many models of maternal undernutrition during pregnancy have examined mild, moderate, or severe caloric restriction (~70%, ~50%, and ~30% of ad libitum caloric intake, respectively) before, for part of, or the entirety of pregnancy to recapitulate adaptations made by the fetus in the context of human dietary restriction. Consistent with human observations, 50% caloric restriction during the latter half of pregnancy in rats produced growth restricted offspring, which display catch up growth postnatally, decreased pancreatic beta-cell mass in infancy and continued impairment of insulin production into adulthood (Garofano et al., 1997). In a similar model in which 50% dietary restriction was imposed for the entire pregnancy, the same trends in neonatal and adult weights were observed, and it was found that intra-abdominal fat mass was increased, with a concomitant reduction to lean body mass (Suzuki et al., 2010). Interestingly, even a modest reduction of 20% global caloric restriction has been shown to decrease offspring insulin sensitivity, an effect thought to be mediated by defects in insulin receptor signaling (Palou et al., 2012), which has even been recapitulated in human studies of men born with a low birth weight (Ozanne et al., 2005). Similar outcomes have been shown in insulin activity and blood pressure regulation in Guinea pig models, consistent with human observations (Cañas et al., 2017; Elias et al., 2016). Caloric restriction during pregnancy in rats has been shown to induce maternal-derived long chain polyunsaturated fatty acids mobilization from adipose and even neural tissue to protect the brain growth of the fetus (Agale et al., 2010). Caloric restriction also compromises reproduction function and has been proposed to result in early ovarian aging and reduced fertility in female offspring (Chan et al., 2015).

In contrast to rodent studies, caloric restriction in sheep at any point of gestation, appears to have negligible effects on birth weight (Fainberg et al., 2013; Gardner et al., 2004; Sébert et al., 2009). Global nutrient restriction during the first 30 days of pregnancy (where full gestation is 147–150 days), does not change birth weight or postnatal weight gain up to 1 year, but does impair baroreflex response, a key homeostatic mechanism in regulating blood pressure, indicating a predisposition to developing cardiovascular dysfunction in offspring (Gardner et al., 2004). While birth weight generally remains unaffected in sheep, lipid deposition has been observed in visceral tissues, including the heart (Ojha et al., 2015), and maternal undernutrition appears to make offspring more susceptible to the negative impacts of an obesogenic diet in adulthood (Chan et al., 2009; Fainberg et al., 2013; Hyatt et al., 2011).

Protein restriction

The Aberdeen cohort studies highlighted that a balance between macronutrients, especially protein and carbohydrates is as equally important for proper fetoplacental development as adequate calorie intake. In this regard, animal models have also used isocaloric, low protein diets to examine the effects of nutrient imbalance on long term disease risk. Pregnant rats have served as the most prominent model showing that low protein diets during pregnancy (50%–70% reduction in protein) result in several postnatal phenotypes that mirror observations in human famine cohorts. Maternal dietary protein restriction consistently impairs growth, reducing birthweight and cardiovascular and renal function (Gao et al., 2013; Hoppe et al., 2007; Koshy et al., 1975; Lim et al., 2010; Rosario et al., 2011). Hypertension in offspring appears to be associated with changes in the number of cardiomyocytes and nephrons, the functional units of the heart and kidney. Like caloric restriction, protein deprivation also induces insulin resistance in offspring (Duque-Guimarães and Ozanne, 2013).

Impacts on the placenta

While observations in fetal outcomes are important in determining how changes in nutrient intake mediate long term health and disease, perhaps of more importance is how these adaptive changes come about. The placenta is a conduit between the maternal and fetal environments. It is generally agreed that changes in placental growth, development, and function in the face of altered nutrient availability likely initiate many of the fetal adaptations that accompany offspring disease outcomes. Both pre-conceptional and gestational undernutrition, impaired placental blood flow, and reduced nutrient availability restrict transplacental nutrient transport to the fetus, a condition known as placental insufficiency. Indeed, placentae of pregnancies complicated by IUGR have increased vascular resistance, decreased surface area available for nutrient transfer, and decreased expression of amino acid and glucose transporters (Mayhew, 2003; Regnault et al., 2005; Rosario et al., 2011). This has been demonstrated in both human and experimental animal models of caloric and protein restriction.

In addition to providing an interface for nutrient and waste exchange, the placenta also serves as a barrier. Maternal glucocorticoids restrict fetal growth (Seckl, 1997). Placental 11 β -hydroxysteroid dehydrogenase Type 2 (11 β -HSD2) serves as an enzymatic barrier that converts bioactive cortisol into an inactive keto metabolite, cortisone (Seckl, 1997). Studies in both humans and other mammalian models have demonstrated that this barrier is disrupted during IUGR, resulting in increased fetal exposure to maternally derived corticosteroids, retarding growth, impairing nutrient transport, and contributing to postnatal offspring disease outcomes (Belkacemi et al., 2011; Connor et al., 2009; McTernan et al., 2001).

While science has made great advances in understanding the signals that mediate maternal-fetal interactions and long-term disease risk, our understanding is far from complete. While some animal data are consistent with human observations, undernutrition does not induce low birthweight or a dysfunctional adult phenotype in all models. This disparity is likely the result of how and when a nutritional challenge is applied, the length of the restriction, the species used and the methods by which phenotypic outcomes are evaluated. While discrepancies do exist, together this body of evidence supports a causal role for early life nutrient-mediated postnatal insulin resistance and impaired hepatic and pancreatic function in an effort to confer improved postnatal fitness, but in many circumstances, predisposing offspring to NCDs including Type 2 diabetes and obesity later life.

Micronutrient Deficiencies

Macronutrients are not the only nutritional factors influencing pregnancy outcomes. Proper intake and supplementation of essential vitamins and minerals, collectively known as micronutrients, are critical for a healthy pregnancy. Among the numerous micronutrients supplied through our diet, there are six that are closely monitored and/or supplemented during pregnancy to ensure appropriate fetal development and maternal health during pregnancy. These include: iodine, iron, vitamin A, folate (vitamin B9), vitamin B12, and vitamin D. Iodine is normally supplemented during pregnancy to promote adequate levels of transplacental transfer of maternal thyroxine to the fetus, to aid in proper neurological development. Iron supplementation, along with vitamin B12 and folate, prevent anemia and ensure adequate red blood cell production. Vitamin A contributes to retinoic acid metabolism, which is imperative for proper cellular differentiation in early development, including formation of neural and cardiac tissues (Bailey et al., 2015). Micronutrient deficiencies (MNDs) can have long-lasting, even permanent consequences for fetal, infant, and adult health, including impaired uteroplacental blood flow, neural defects, changes to metabolism and altered whole body adiposity (Rao et al., 2012). Iodine, iron, vitamin A, and folate deficiencies are among the leading causes of MNDs globally, and primarily affect populations in low-to-middle income countries (Bailey et al., 2015).

Iron

Iron deficiency is the most common MND worldwide, affecting an estimated 2 billion people. Iron deficiency causes anemia, due to lack of iron available for formation of hemoglobin, and is particularly common in pregnant women because of increased demand for iron for the development of the fetoplacental circulatory system (Bailey et al., 2015). Maternal iron deficiency is associated with low birth weight, preterm birth, maternal hemorrhage, and impaired immune system development in neonates (Cornock et al., 2013; Fu et al., 2012). It is routine to supplement dietary intake of iron to avoid these complications. In rat models, iron deficiency during pregnancy induces placental *hypoxia* and *oxidative stress*, which has growth restricting effects (Toblli et al., 2012). Maternal iron deficiency prior to and during pregnancy in mice decreases the number of live pups at birth, fetal body weight, and crown-rump length (Hubbard et al., 2013). Alterations to fetal mouse and postnatal rat, guinea pig, and human brain and liver fat metabolism have also been observed in response to prenatal iron deficiency and anemia (Rao et al., 2012). While mechanisms by which iron deficiency and maternal anemia remain under studied, it is undeniable that maternal iron status is critical for short and long-term health outcomes for the next generation.

Folate

Folate is found abundantly in green leafy vegetables and legumes. Once consumed, folate is converted to tetrahydrofolate (THF) which, along with vitamin B12, are key co-factors in one-carbon metabolism, modulating cellular processes including DNA synthesis and *epigenetic* modifications, including DNA methylation. As such, folate intake is critical for maintaining appropriate methylation and control of gene expression throughout development and postnatal life. Folate deficiency during pregnancy results

in macrocytic or megaloblastic anemia, and failure of embryonic neural tube closure, resulting in neural tube defects (NTDs) (Bailey et al., 2015). The incidence of NTDs decreased drastically with the introduction of folic acid fortification and supplementation during pregnancy, where it is recommended that pregnant women receive an additional 400 µg per day of folate. Unfortunately, no reliable estimates exist of how many women at high risk of pregnancy complications experience folate acid deficiency (Bailey et al., 2015).

Experimental evidence from mouse and rat models has suggested that folate also plays an important role in decidual angiogenesis. Folate deficiency prior to pregnancy in mice causes impaired decidual apoptosis, preventing decidual remodeling for embryonic implantation and impairments in the generation of maternal blood sinuses (Li et al., 2015b; Liao et al., 2015). This could have several implications for both the mother and child, including pre-eclampsia. Clinically, folate deficiency has been associated with IUGR and preterm delivery (Singh et al., 2015). The role of folate (in)sufficiency does not end with the mother, however. Recently, paternal folate deficiency, among other factors, has been implicated in fetal development, pregnancy outcomes, and disease outcomes (Lambrot et al., 2013). Paternal folate deficiency is hypothesized to alter sperm epigenome and impair proper expression of key genes involved in placentation and placental function. As previously mentioned, placental insufficiency is a prominent cause of growth restriction and metabolic programming outcomes, as seen in cases of macronutrient restriction. The extent to which paternal nutrient challenges influence pregnancy outcomes is highly debated. Only time and more experimental work will tell how much a father's nutritional status can impact a child before they are born.

Maternal Nutrient Excess

While negative energy balance and famine have clear associations with harmful outcomes at birth and postnatally, a positive energy balance, in the form of excess calorie intake, weight gain, and obesity, have equally adverse effects on maternal metabolism and on pregnancy outcomes. Overweight and obesity are often accompanied by increased levels of circulating pro-inflammatory cytokines, insulin resistance, glucose intolerance, and increased circulating levels of gut-derived bacterial endotoxins in the mother. Additionally, inflammation is also manifest within metabolic tissues of obese individuals including the liver, adipose, and pancreas, marked by increased infiltration of immune cells and in situ pro-inflammatory cytokine production.

Epidemiological Evidence

Excess adiposity during pregnancy (EADP) has become a worldwide concern in recent years, especially in Westernized countries. Globally, 39% of adults are overweight and 13% are considered obese (WHO | Health in 2015). This widespread epidemic has resulted in nearly 1 in every 2 women entering pregnancy overweight, or gaining more weight than is recommended throughout gestation (Dudenhausen et al., 2015). Overweight women (BMI > 24.9) are at an increased risk of developing gestational diabetes mellitus, preeclampsia, macrosomia, and delivering by C-section. Women considered morbidly obese (BMI > 40.0) are at an even higher risk of these same complications, being five times as likely than lean women to develop pre-eclampsia and three times as likely to deliver a stillborn child. Furthermore, children of obese women are over three times as likely to die in the neonatal period (Cedergren, 2004).

The consequences of nutritional excess during gestation do not end in early neonatal life, however. EADP can induce several postnatal effects, much like the effects of undernutrition, with implications for long term offspring health. Maternal obesity is the strongest predictor of offspring obesity and the metabolic syndrome (Ong et al., 2015; Patro et al., 2013). Insulin resistance, Type 2 diabetes, hypertension, and cardiovascular disease also accompany these outcomes. Maternal overweight and obesity are associated not only with giving birth to a large for gestational age baby, but also with preterm and/or IUGR neonates (Higgins et al., 2011; Radulescu et al., 2013). While this may seem counterintuitive, some evidence from humans and animals suggest that despite consuming excess calories, a poor quality of diet and lack of physical activity can, in some cases, impair embryo placentation and disrupt maternal uterine blood flow, restricting fetal access to maternal (micro)nutrient stores, resulting in growth restriction (Fig. 2). This has been an area of intense investigation using animal models.

Experimental Models

Like models of undernutrition, models of maternal nutrient excess have primarily used sheep and rodents, with the latter including many studies of diet-induced obesity in mice and rats. In general, three dietary models have been primarily used: Western-style diets (WS, ~40% kcal from simple sugar, ~40% kcal from animal fat), high fat diet (HF, 45%–60% kcal from animal fat) and high fructose diets (HFr, 50%–70% kcal from fructose). Several studies use these obesogenic diets to prime mothers prior to pregnancy to mimic the overweight phenotype of women with high pre-pregnancy BMI. These studies have shown that maternal obesity programs offspring obesity independent of the offspring's postnatal diet, cementing the role for in utero exposures as a key for the development of later life metabolic disease (Howie et al., 2009). In rodent models, it has been demonstrated that offspring exposed to an adverse environment in the form of maternal obesity leads to IUGR in some but not all cases (Howie et al., 2013).

Diets supplemented with fructose, high fructose corn syrup (HFCS), or common sweeteners used in both food and beverages have also been shown to have adverse effects when consumed in excess. Studies have demonstrated that excess maternal intake of fructose, unlike its structural isomer glucose, does not promote insulin and leptin secretion, resulting in calorie consumption

Fig. 2 A constellation of nutritional factors impact cardiometabolic programming of offspring disease. Maternal energy balance and dietary quality directly impact placentation and concomitant nutrient transport to the fetus, with downstream consequences for fetal metabolic adaptation to perceived postnatal nutritional availability. Adaptations made in the womb interact with the postnatal nutritional environment to drive development of chronic disease. Metabolic disease, including obesity and type 2 diabetes may act as stimuli driving the production of transgenerational programming effects. *Denotes features of the metabolic syndrome.

without promoting a feeling of fullness (Sloboda et al., 2014). Furthermore, excess fructose is preferentially used as a lipogenic substrate, resulting in conversion to lipids and storage in adipose tissue (Sloboda et al., 2014). Excess fructose consumption results in hyperinsulinemia, hypertriglyceridemia, hypertension, non-alcoholic fatty liver disease (NAFLD), and leptin resistance in rat models (Goran et al., 2013). While many studies use supraphysiological levels (> 50% of total caloric intake) of fructose to induce obesity, physiologically relevant intakes (i.e., 10% fructose solutions in drinking water or 20% of total caloric intake) have also been shown to induce maternal hyperinsulinemia, hypertriglyceridemia, altered liver metabolism, and impaired maternal and fetal leptin signaling (Goran et al., 2013; Sloboda et al., 2014). As might be expected, these changes in maternal physiology during pregnancy are associated with changes to neonate metabolism, with or without alterations to birth weight and placental growth. Despite obvious detrimental effects, there is a paucity of data examining the severity of programmed effects and the efficacy of intervention beyond the neonatal period.

Placental growth, hypoxia, and inflammation

As demonstrated in undernutrition models, many of the contributing factors underpinning the programming of disease risk are believed to originate with altered placental function. Studies of human term placentae as well as those in animal models have indicated several common placental phenotypic characteristics including altered vascularization and growth, inflammation, and placental hypoxia.

Vascularization of the placenta, invasion into the maternal decidua, and proliferation of trophoblast tissue are of great importance in ensuring adequate energy supply and waste exchange throughout the course of pregnancy. In an ovine model of nutrient excess during pregnancy placental vascularization in early to mid-gestation was impaired, resulting in reduced placental size in late gestation (Redmer et al., 2009). In a mouse model of maternal obesity during pregnancy, it was found that term placentae (gestational day 18) had decreased levels of mTOR signaling, a key signaling cascade in cellular growth, proliferation, and invasion as well as nutrient sensing (Lager et al., 2014). Placental mTOR levels are decreased in models of undernutrition as well, highlighting the importance of this pathway in modulating placental growth and the growth capacity of the fetus.

Inflammation, a common hallmark of obesity, has been seen in human, ovine, and rodent placentae from pregnancies complicated by nutrient excess and/or obesity. These placentae show increased immune cell infiltration, expression of pro-inflammatory markers (interleukins (IL) 1, 6, 8, and tumor necrosis factor (TNF)), or changes to immune cell phenotype (Challier et al., 2008; Zhu et al., 2010). Placental and decidual tissues contain within them several innate immune cell populations responsible for remodeling vasculature during placentation. Increased exposure of these cells to inflammatory cytokines may impair their acquisition of phenotypes promoting tissue remodeling to an inappropriate pro-inflammatory state, impairing proper embryo implantation and subsequent fetoplacental growth throughout gestation (Hemberger, 2013). Increased exposure to inflammation can have deleterious effects on both fetal growth and postnatal metabolic homeostasis (Ingvorsen et al., 2015). Moreover, many cytokines modulate placental nutrient uptake and can cross from maternal to fetal circulation which promote fatty acid uptake, and mobilization of maternal glucose to the fetoplacental unit (Segovia et al., 2014). As such, innate immune cell invasion and their phenotype in the placenta, and cytokine exposure in utero likely represent potent programming stimuli of postnatal metabolic homeostasis (Fig. 2).

Maternal Gut Microbial Health—A Novel Programming Factor

Increasing evidence suggests that the processing of nutrients by intestinal (gut) commensal bacteria has implications for offspring development. The human gut is a reservoir for trillions of commensal organisms commonly referred to as our microbiota. These microbes, the genes they encode and their products are collectively referred to as our gut microbiome. The microbiota plays several key roles in both host immunity and metabolism. Gut bacteria function to produce essential micronutrients including vitamin K2, biotin, and folate, they metabolize indigestible dietary fibers, and produce short chain fatty acids which modulate a variety of host metabolic functions such as gastrointestinal motility, hormone secretion, as well as gut immune cell function and epithelial barrier integrity (Macpherson and Harris, 2004; O'Hara and Shanahan, 2006). Experimental evidence from mice lacking any commensal organisms, (germ free (GF) animals), suggests that GF mice require a higher caloric intake to maintain the same body weight as their colonized counterparts, highlighting the importance of commensal microbes in mediating proper nutrient absorption and metabolism (Bäckhed et al., 2004).

The microbiota can also contribute to disease pathophysiology and one area of primary interest is the development and maintenance of chronic low grade systemic inflammation seen in obese individuals. Significant shifts occur in the composition of the gut microbiome in the context of obesity (Albenberg and Wu, 2014). Obesity-induced shifts in the microbiota are often accompanied by elevated levels of bacterial component including LPS (Cani et al., 2008; Erridge et al., 2007). LPS induces inflammation through the activation of innate immune receptor signaling pathways leading to production of pro-inflammatory cytokines. Increased circulating LPS in the context of obesity, is likely the result of decreased intestinal barrier function and increased permeability to bacterial components.

Recent evidence suggests that host-microbial interactions may mediate maternal metabolic adaptations made during pregnancy to support the growth of the developing embryo and fetus. In a landmark paper by Koren et al. (2012), it was demonstrated that the composition of the gut microbiota changes over the course of pregnancy, and that changes in third trimester composition can induce increased intestinal inflammation, adiposity, and insulin resistance, as compared to first trimester, when transplanted

into germ free mice. These changes are consistent with the progressive metabolic adaptations made by women throughout normal pregnancy. Following this work, [Gohir et al. \(2015\)](#) showed that the native microbial communities in mice undergo shifts during normal pregnancy, and that the specific changes that occur are dependent on the maternal peri-conceptual diet. Given the known role of the microbiome in modulating host metabolism, immunity, and inflammation, it is likely that this area of research will provide novel insights into the mechanisms by which diet influences pregnancy outcomes and offspring disease risk, providing new avenues for intervention during pregnancy to improve outcomes for both mother and child.

Nutritional Interventions to Reverse or Ameliorate Impacts of Maladaptive Early Life Nutritional Programming

The programming of postnatal disease through adaptations that occur early in life was once considered to result in irreversible changes in developmental trajectory via permanent resetting of the homeostatic mechanisms involved in growth and metabolism. However, it has now been shown, at least in animal models, that these effects can be reversed via targeted nutritional interventions during critical early life windows of developmental plasticity.

Methyl Donors

There has been increasing attention given to *epigenetic* processes as likely mediators of gene expression with changes in DNA methylation, histone modification and miRNAs in offspring all shown to arise as a consequence of early life nutritional insults. Maternal dietary *methyl donor* supplementation including the addition of choline to the maternal diet for example, in the setting of low protein (MLP) exposure, can prevent the increases in adiposity and blood pressure observed in offspring of non-supplemented mothers ([Bai et al., 2012](#)). Maternal glycine supplementation has been similarly shown to prevent increased systolic blood pressure in MLP offspring ([Jackson et al., 2002](#)), by correcting the vascular dysfunction that arises due to protein restriction ([Brawley et al., 2004](#)). Folic acid supplementation can also prevent hypomethylation of hepatic gene expression in offspring (including peroxisomal proliferator-activated receptor (PPAR)-alpha and glucocorticoid receptor (GR) genes) ([Lillicrop et al., 2005](#)).

Taurine

Maternal taurine, a sulfonated amino acid, supplementation in the MLP rat can normalize the vascularization of the fetal endocrine pancreas ([Boujendar et al., 2003](#)) and can partially prevent the adverse effects associated with protein restriction on pancreatic β -cell function and insulin sensitivity ([Boujendar et al., 2002](#); [Cherif et al., 1998](#); [Tang et al., 2013](#)). Since mitochondrial dysfunction may predispose to the development of Type 2 diabetes in adulthood, taurine deficiency may be a key causative factor, since taurine supplementation has been shown to restore low protein-induced changes in pancreatic islet mitochondria ([Lee et al., 2011](#)). In the setting of maternal obesogenic diets, fructose-induced metabolic and inflammatory dysregulation in offspring can also be partially reversed via maternal taurine supplementation ([Li et al., 2015a](#)). Similarly, in the setting of a maternal HF diet, supplementation with taurine results in beneficial changes in hepatic markers of inflammation and lipid metabolism in offspring. However, in this case, taurine supplementation resulted in hepatic pro-inflammatory phenotype in the mothers and thus may suggest a possible maternal “trade-off” to protect the neonate. Further, despite taurine conferring some protection against programming-related disorders in offspring of obese mothers, there was a significant increase in neonatal mortality in neonates born to taurine supplemented control mothers, indicative of possible adverse effects of taurine in the setting of normal pregnancy ([Li et al., 2013](#)).

Linoleic Acid

In rats, conjugated linoleic acid (CLA), an omega 6 fatty acid, has shown efficacy in reversing metabolic disorders in offspring born to mothers fed a HF diet. Developmental programming of endothelial dysfunction, hypertension, impaired insulin sensitivity, skeletal muscle atrophy, and inflammation in male rat offspring was partially improved by maternal CLA supplementation ([Gray et al., 2015](#); [Pileggi et al., 2016](#); [Segovia et al., 2015](#)). Which also ameliorates maternal HF diet-induced programming of inflammatory gene expression in the gut of rat offspring ([Reynolds et al., 2015](#)).

Micronutrient Supplementation

Given that maternal obesity results in oxidative stress the use of antioxidants as a reversal agent has also been investigated. In HF fed rats supplemented with antioxidants (including vitamins A, C, and E, and selenium), adiposity was decreased and glucose tolerance normalized as compared to non-supplemented mothers ([Sen and Simmons, 2010](#)). Dietary intake of the antioxidant coenzyme Q10 has also been shown to ameliorate programmed disorders in the rat. In maternal low protein diets Q10 supplemented offspring have reduced oxidative stress, inflammation and insulin levels compared to non-supplemented counterparts ([Tarry-Adkins et al., 2015, 2016](#)). Polyphenols including resveratrol decrease oxidative stress where in the setting of a MLP diet, resveratrol partially prevented alterations in maternal, placental and offspring markers related to oxidative stress and metabolic function ([Vega et al., 2016](#)).

Considerations and Future Directions

The experimental interventions trialed to date, does not represent a “one size fits all”. Taurine supplementation for example, may ameliorate metabolic defects in the setting of nutritional adversity but in a normal pregnancy may have deleterious effects on both mother and offspring, possibly via hypoglycemic effects of taurine (Li et al., 2013). Similarly, maternal folic acid supplementation intakes has been associated with increased incidence of respiratory impairment, and increased folate status during pregnancy has been linked to insulin resistance in children (Burdge and Lillycrop, 2012). Given the high proportion of women that take nutritional supplements during pregnancy, the evidence surrounding maternal methyl donor and vitamin supplements, one carbon metabolism and altered DNA methylation patterns would suggest that more attention needs to be given to the safety and potential long-term effects of such supplements on later offspring outcomes (Vanhees et al., 2014). Thus, identifying those at potential risk is an important consideration when nutritional intervention strategies are implemented as in some settings have the potential to induce harm.

Concluding Remarks

The last 30 years have provided undeniable evidence that maternal nutrition before, during, and shortly after pregnancy can have a profound impact on next generation health, well beyond fetal and neonatal life. Proper caloric intake, balanced macronutrient consumption, and micronutrient sufficiency are of utmost importance in ensuring not only the proper development of the fetus, but also in attenuating risk of chronic disease risk in later life. While beyond the scope of this article, it is worth noting that many of the negative cardiometabolic impacts of fetal programming are not confined to a single generation. As the fetus develops, so do its germs cells, which will give rise to gametes that form grand-offspring. As such, more than one generation is exposed at a time to the effects of maternal malnutrition in utero. What is more, many of the metabolic consequences for which the fetus is primed in later life (i.e., obesity and diabetes) may act as programming stimuli on subsequent generations as well. This, along with heritable changes in epigenetic marks are thought to be responsible for multi- and transgenerational metabolic programming effects. Malnutrition during pregnancy is a single, albeit powerful, factor in a constellation of interacting stimuli which can be deleterious to fetal development and increase later life disease risk, including maternal stress, smoking, recreational drug use, alcohol consumption, prescription medication use, and environmental toxicant exposure. Finally, it has been demonstrated that fetal programming of metabolic disorders is not an entirely irreversible process, with several interventions offering promising outcomes for offspring health. To date, in human populations at least, adequate and balanced nutrition during preconception, gestation, and the early neonatal period undoubtedly remain the best, most efficient way to ensure a positive contribution of maternal nutrition to perinatal and adult health. In cases where programming effects are unavoidable, future research into understanding the complex mechanisms underlying fetal adaptations to maternal nutrition will be invaluable in the development of targeted therapies that can be applied both during pregnancy and in early life to attenuate undesirable health outcomes.
